Supporting this view are English experiments in which chicks placed in isolation boxes immediately after being hatched showed no response to a penicillin supplement.[179] On the other hand, when a small amount of intestinal contents of normally housed chicks was mixed with the feed, penicillin gave a marked growth stimulation. Similarly, in an experiment at Notre Dame University chicks raised under germ-free conditions did not respond to an antibiotic supplement.

It was found in these studies that the intestinal wall was thinner in the uninfected chicks or in the infected chicks fed the antibiotic than in chicks raised under normal conditions. This might increase the efficiency with which nutrients are absorbed.

In certain recent experiments chicks kept under practical conditions have responded much less, or not at all, to an antibiotic feed supplement, while in previous years the growth stimulation on similar rations had been marked.[180] It is believed that this difference was due to the reduction in harmful bacteria brought about by the continued use of an antibiotic supplement in the preceding years.

An antibiotic feed supplement tends to increase appetite and feed consumption. It may also stimulate the pituitary gland, so that more growth hormone is produced. Possibly, an antibiotic supplement may increase the efficiency with which protein is utilized, or decrease the need for certain vitamins. Also, certain studies indicate that an antibiotic feed supplement may increase the assimilation of calcium. Experiments have shown that an antibiotic supplement does not generally increase the digestibility of a ration.

A beneficial effect of an antibiotic-B_{12} feed supplement may be due to the B_{12} content as well as the effect of the antibiotic.

In most of the experiments with dairy calves, especially those weaned from milk at a very early age and fed a milk substitute, a suitable antibiotic feed supplement has generally increased the gain during the first 2 or 3 months. However, by the time the calves are 6 months old or older, there may be little or no difference in weight. In some trials the antibiotic has reduced trouble from scours during the first few weeks.

It has generally not been beneficial to add an antibiotic or antibiotic-vitamin B_{12} feed supplement to ordinary rations for dairy cows, for dairy heifers over 4 to 6 months of age, or for brood sows. Conflicting results have been secured from antibiotic feed supplements with beef cattle and sheep.

As is shown in Chapter XXXVI, the results have also differed in experiments where an antibiotic feed supplement has been added to rations for laying hens. The supplement often does not increase the egg production of hens fed a nutritionally complete ration which are laying at a high level, but may be beneficial at a lower level of production or with a poorer ration.

An antibiotic-vitamin B_{12} feed supplement is now included in a large proportion of the commercial mixed feeds, or "formula" feeds, for chicks and broilers, for growing and fattening pigs, and for young dairy calves (especially in milk replacers). The amount of such a supplement to be added to a feed mixture is so small (usually only 10 lbs. or less per ton) that it is difficult to mix it thoroughly by hand.

Many different antibiotics have been discovered, and several different antibiotic feed supplements are on the market. The effectiveness of various antibiotics apparently differs widely, and some produce no increase in growth. The reputation of the feed manufacturer for producing feeds of high quality and efficiency is therefore the best guide in purchasing formula feeds containing an antibiotic feed supplement.

967. Arsonic supplements; surfactants.—In a few experiments certain *arsonic compounds* (including arsanilic acid and other derivatives of arsonic acid), when added to a good ration, have generally, but not always, had an effect upon chicks and poults somewhat similar to that of an antibiotic. In certain trials an arsonic supplement has even stimulated growth when added to a ration containing an effective antibiotic. There is as yet but little experimental data concerning the effect of an arsonic supplement on laying hens.

Data are yet too limited to show definitely whether there will be an appreciable advantage for healthy young pigs from adding an arsonic supplement to a good ration that contains an effective antibiotic. In herds where there has been much trouble from dysentery in young pigs, an arsonic supplement may reduce the trouble.

The data concerning the effect of an arsonic supplement on young dairy calves are yet too limited to warrant conclusions. In Illinois experiments with fattening lambs it was concluded that 3 arsonic supplements tested were not beneficial.[181]

If an arsonic supplement is used, care must be taken so that safe levels are not exceeded. Experiments have shown, when properly fed, meat does not contain as much arsenic as permitted under regulations. As a precaution, the law requires that feeds containing such compounds must not be fed for at least 5 days before slaughter for human food.

Further information on arsonic supplements for pigs, poultry, and dairy calves is given in the chapters dealing with these classes of stock.

Much interest has been shown in the addition of certain surfactants (surface active agents) to feeds. In most of the experiments so far conducted, mostly with chicks and young pigs, little effect has been noted.

Tests with a new "chemobiotic" (tetra alkylammonium stearate) have given variable responses when added to rations

of ruminants and pigs. No apparent benefit was obtained in tests at Purdue or Iowa while Montana and Washington have reported increases in gain and feed efficiency from its use in beef cattle rations. Further information about surfactants is given in the chapters dealing with the feeding of swine, poultry, and dairy calves.

968. Complex mineral or vitamin mixtures; enzyme preparations; stock tonics.—Many complex mineral mixtures for stock feeding are extensively advertised, as are also preparations including both minerals and vitamins. Some of the mineral mixtures are honest efforts to supply at a reasonable price the minerals which may be lacking in certain rations. Extravagant claims are made for others, or they are sold at excessively high prices or are even of poor quality.

Many commercial mineral mixtures are high in calcium and rather low in phosphorus. This is because ground limestone or another calcium supplement is so much cheaper than a safe phosphorus supplement. Such a mineral mixture is generally very uneconomical and may even be detrimental where the animals already have plenty of calcium but lack phosphorus.

It has been pointed out in Chapter VI that simple mineral mixtures, such as are there recommended, will produce just as good results as complex mixtures that contain a large number of ingredients. (**187**) One cannot therefore afford to pay much more for a commercial mineral mixture than it would cost to make up a suitable mixture on the farm.

The vitamin requirements of farm animals have been considered in detail in Chapter VII. It has there been shown that, for all livestock except poultry, an ample supply of the necessary vitamins can generally be provided in rations made up of common feeds, without the use of special vitamin supplements. There is usually no benefit from adding yeast to ordinary rations, except in the case of poultry or swine fed rations deficient in B-complex vitamins. (**210**)

In spite of claims that are sometimes made to the contrary, there is no scientific evidence that any mineral mixture or vitamin supplement will prevent or cure Bang's disease (contagious abortion) in cattle. This disease must be clearly distinguished from the rare cases of abortion that may be produced by a serious lack of vitamins or minerals.

Sometimes claims are made that certain enzyme preparations will greatly improve livestock rations. The author knows of no scientific evidence that such preparations improve ordinary rations. It has been shown in Chapter IV that methods which have been exploited for fermenting, malting, or pre-digesting feeds do not cause any saving of feed or result in greater production. (**94**)

In spite of the advice of the experiment stations to the contrary, some farmers still spend money for various products called "stock tonics," etc. Tests of many stock tonics by the experiment stations show clearly that there is generally no advantage in their use. Farm animals managed with reasonable care have appetites which do not need stimulating. Sick animals or those out of condition should receive specific treatment rather than be given some cure-all.

The testimonials which the stock-tonic companies advertise are readily explained. The stock tonics are usually accompanied by directions which advocate liberal feeding and good care for the animals to be fed, in order to "secure the benefits from the tonic." The farmer therefore feeds and cares for his stock better than ever before and secures better results, due not to the tonic but to following the directions which accompanied it. Rather than purchase advice with costly tonics, the wise feeder will secure it in standard agricultural papers and books, or from the experiment stations and the United States Department of Agriculture.

VI. Miscellaneous Concentrates and Other Products

969. Apples and other fruits.—Windfall and surplus apples and other fruit can sometimes be fed advantageously to stock. Apples, peaches, plums, and even pears contain somewhat more dry matter than do

such roots as mangels and rutabagas. The chief nutrients are sugars, and fruits are extremely low in protein.

In a Virginia experiment in which dairy cows were fed 36 lbs. of apples per head daily in addition to hay and concentrates, it was concluded that a pound of dry matter in the apples was nearly equal to a pound of dry matter in corn silage and slightly superior to a pound in hay.[182] On this basis apples would be worth about 60 per cent as much per ton as corn silage. If cows have access to all the apples they can eat, as in an orchard where there are many on the ground, serious digestive disturbance may result.

In Washington tests good results were obtained when fattening lambs were fed 0.9 to 1.5 lbs. of apples per head daily in addition to hay and grain.[183] Thus fed, apples were even equal to corn silage in value per ton. When larger amounts of apples were fed the results were less satisfactory.

Good silage can be made by chopping a mixture of about 80 per cent by weight of apples and 20 per cent of alfalfa or other good hay, or else 60 per cent of apples and 40 per cent of wilted green hay crop. The loss by drainage is excessive if apples are ensiled alone. Apple-alfalfa silage was about equal to sunflower silage for dairy cows in Washington tests.[184] Silage can be made similarly from apple and pear cores and peelings.[185]

In California tests cows readily ate 20 to 30 lbs. of peaches a day. Only a few of the pits were swallowed.[186] Pears were not quite so palatable. When cows were fed more than about 15 lbs. of fresh prunes a day, scouring resulted. Smaller amounts were satisfactory. Cows could be allowed all the fresh grapes they would eat. None of these fruits injured milk flavor. Dried fruits of these kinds were also satisfactory in suitable amounts.

When apples replaced part of the grain for pigs in Utah trials, it required 9 to 15 lbs. of apples to equal 1 lb. of grain.[187]

In Florida trials fattening cattle made good gains when fed fresh grapefruit with hay, cottonseed meal, and 2 lbs. of corn a day.[188] Well-grown cattle can eat whole grapefruit, but for young animals it is best to quarter or slice the fruit. In another Florida test oranges were less satisfactory for fattening cattle, unless they had been grated to remove the outside of the peel.[189] Pigs made good gains on tangerines when fed an efficient protein supplement, and still better gains when also fed some corn.[190]

A ration of ripe olives and alfalfa produced satisfactory gains on lambs in an Arizona test.[191]

Chopped pineapple tops, or crowns, which form about 7 per cent of the weight of the fresh fruit, were palatable and about equal to green Napier grass as the only roughage for dairy cows or dairy heifers in Hawaiian experiments.[192] The cows ate 60 lbs. or more of the tops per head daily.

In a Guatemala trial ripe bananas, including the skins, were a satisfactory and economical feed for growing and fattening pigs, when as much as 2 lbs. of bananas was fed with each pound of a high-protein concentrate mixture.[193]

In Hawaiian trials bananas and avocados were economical supplemental feeds for laying hens, but the feeding of papaya over a long period of time produced detrimental results.[194]

970. Apple pomace; apple pectin pulp.—*Wet apple pomace* is the by-product when the juice is expressed from apples for cider or vinegar. It may be fed fresh, it may be ensiled, and it is sometimes dried to make *dried apple pomace.*

Wet apple pomace and apple pomace silage have about 21 per cent dry matter, in comparison with 27 per cent for silage from well-matured corn, and they are very low in protein. Though apple pomace silage is slightly lower in total digestible nutrients than average corn silage, it has proven about equal to corn silage in value per ton for dairy cows.[195] It should be fed after milking, to avoid tainting the milk. Unless stray box nails are removed from the apples or pomace at the mill, there may occasionally be injury to cattle from this source.

Dried apple pomace has given satisfactory results when used like dried beet pulp in dairy rations, and has been worth 75 per cent as much per ton as dried beet pulp or even more.[196] Fed as one-third the concentrates to fattening cattle in a Washington trial, dried apple pomace produced slightly less rapid gains than did dried molasses-beet pulp.[197] Because more protein supplement was needed with it, the apple pomace was worth only 57 per cent as much as the dried molasses-beet pulp.

Apple-pectin pulp is the residue left when the pectin is extracted from apple pomace for jelly making. *Dried apple-pectin pulp* was not as palatable to dairy cows as dried beet pulp in a test by the United States Department of Agriculture, when both were fed after soaking with water.[198] This difficulty can be avoided by mixing

the apple-pectin pulp with well-liked concentrates.

971. Bakery waste.—Sometimes stale bread or other bakery waste can be secured at a price that makes it an economical stock feed. Such waste can be used in place of part of the grain usually fed. Since bread usually contains over 30 per cent water, its feeding value is only about three-fourths that of corn or other grain.

Kiln-dried bakery waste is similar to grain in composition, except that it is lower in fiber and may be higher in fat. In Pennsylvania trials kiln-dried stale bread, fed after being moistened with water, was about equal to corn for pigs on pasture, but was constipating unless fed with some laxative feed.[199] Stale crackers were somewhat less valuable.

972. Cassava meal.—This by-product, also called tapioca meal, manihot meal or manioc meal, is produced in the manufacture of starch from the roots of the tropical cassava. It is rich in nitrogen-free extract and low in fiber, but is unusually low in protein and fat. It may be used as a substitute for part of the grain in feeding dairy cows and other stock, being approximately equal to grain in value, except for its lowness in protein.[200] In German trials it was concluded that not more than 10 per cent should be included in a ration for chicks, or the feed consumption would be decreased.[201]

973. Chicken litter.—Because ruminants can use non-protein nitrogen as a partial substitute for protein, experiments have recently been conducted at the Arkansas Station to find whether chicken litter, including the manure, could be used as a substitute for ordinary protein supplements in feeding beef cattle and sheep.[202] The dry chicken litter had an average of 4.6 per cent nitrogen, equivalent to 28.8 per cent crude protein. About one-fifth of the nitrogen was uric acid, which is the chief nitrogenous waste product in the case of birds.

In a test with ewes during gestation and lactation, the results were satisfactory when 23 per cent of dry chicken litter was included in the concentrate mixture, replacing soybean oil meal. In a trial with fattening lambs, 23 or 42 per cent of dry chicken litter was included in a pelleted mixture having 10 per cent of cane molasses. The gains were nearly as good as on a ration with cottonseed meal as the protein supplement. On the basis of feed required per 100 lbs. gain, 100 lbs. of chicken litter was equal to 63 lbs. other concentrates minus 15 lbs. hay.

Differing from these results, in a trial with fattening steers, the gain was decidedly less on a mixture containing 25 per cent dried chicken litter than on the check concentrate mixture, unless considerably more feed was given the steers fed chicken litter. On the basis of the feed required per 100 lbs. gain, 100 lbs. of chicken litter replaced only 9.2 lbs. other concentrates minus 28.8 lbs. hay.

974. Citrus pulp and other citrus by-products.—*Citrus pulp* is a by-product of citrus-canning factories, which make citrus fruit juices, canned fruit, and other products. It consists of the peel, the residue of the inside portion, usually including the seeds, and occasional cull fruits, with or without the extraction of part of the oil of the peel for flavoring extracts. Certain factories remove the seeds, which are processed for oil production, with *citrus seed meal* as a by-product. Citrus pulp is generally dried and ground, and sold as *dried citrus pulp*. The finer particles may be separated and marketed as *citrus meal*, usually at a slightly lower price.

Dried citrus pulp and molasses is also made, usually containing 10 to 33 per cent of citrus or cane molasses.

Before drying the pulp, lime is added to free water which is chemically bound to constituents of the pulp. Then the pulp is pressed to remove as much of the juice as possible. This may be condensed by evaporation to form *citrus molasses*.

Dried citrus pulp somewhat resembles dried beet pulp in composition and nature. It is a little higher in total digestible nutrients, having 74.9 per cent, but is very low in digestible protein, with only 2.7 per cent. Because of the lime added in the drying process, it has 2.04 per cent calcium, but the phosphorus content is only 0.15 per cent.

Dried citrus pulp is made chiefly from grapefruit or orange residue, but in some districts may contain lemon residue. There is not much difference in the composition or value of pulp from the various kinds of citrus fruits, except that lemon pulp is less palatable.

Dried citrus pulp is fed chiefly to dairy cattle and is a satisfactory substitute for dried beet pulp. In 3 Florida experiments it was about equal to dried beet pulp for dairy cows when forming as much as 40 per cent of the concentrate mixture.[203] In other tests it was not considered quite equal to dried beet pulp for milk production.[204] In 5 Texas

trials with dairy cows, dried citrus pulp was nearly equal to corn-and-cob meal (not including husks), when forming half of the concentrate mixture.[205] In an Arizona test dried grapefruit pulp increased the milk production of dairy cows that had declined in milk yield when fed only alfalfa hay.[206]

Though citrus pulp is less palatable than dried beet pulp, there is generally no difficulty in getting cows to eat a concentrate mixture containing it. If a mixture with a large percentage of citrus pulp is to be fed, it is well to increase the proportion gradually. In most of the tests the flavor of the milk has not been affected by dried citrus pulp.[207]

In Arizona trials dried grapefruit pulp was a satisfactory substitute for other concentrates for dairy heifers fed alfalfa hay or on pasture.[208]

Dried citrus pulp is a good substitute for part of the grain in rations for fattening cattle. In Arizona trials it was equal to rolled barley when replacing half of the grain.[209]

Used as a partial substitute for grain in fattening cattle, dried citrus pulp was equal to ground snapped corn, including the husks, in Florida and Texas trials.[210] In the Texas tests the ration tended to be too laxative when it formed one-half of the concentrate mixture. For steers on excellent pasture, dried citrus pulp was satisfactory as the only concentrate in Florida trials, being worth more than cane molasses.[211]

Dried citrus pulp is not suited for use as any important part of a ration for swine[212] or poultry.[213] In a Florida trial 5 per cent of dried citrus meal, (the finer particles) could be satisfactorily fed to pigs.[214]

Dairy or beef cattle eat fresh citrus pulp readily after they become used to it. The pulp may also be ensiled, preferably with chopped hay or fodder, as it is very high in water. When ensiled in trench silos, the shrinkage in weight of pulp was 21 to 43 per cent in Florida and Arizona tests.[215] In the Arizona trials fattening cattle would not eat as much grapefruit-pulp silage as of hegari sorghum silage. Considering the shrinkage of the grapefruit-pulp silage, it was not considered economical, unless the cost of the pulp at the silo was less than 30 per cent of the cost of hegari silage.

Citrus molasses, made from the juice pressed from citrus waste at canning factories, contains nearly as much sugar as does cane molasses. Although it has a very bitter after taste to humans, it is consumed readily by cattle and may be fed them much like cane molasses. As much as 6 lbs. a day has been fed satisfactorily to fattening cattle to replace part of the grain, and it has even been fairly satisfactory as the only concentrate for fattening cattle on excellent pasture.[216] When replacing not more than half the grain for fattening cattle citrus molasses has been nearly equal to ground snapped corn, including the husks, and worth slightly less than ground milo.

In Florida trials pigs did not at first like concentrate mixtures containing citrus molasses, but after a week ate mixtures containing as much as 30 to 40 per cent of the molasses.[217] Fed as 10 per cent of the ration, the molasses was worth 91 per cent as much as corn. The value decreased if the proportion of molasses became larger. Citrus molasses is not liked by horses and mules.

Ten per cent of citrus molasses in a ration for chicks was satisfactory in one Florida trial, but not in another.[218]

Citrus seed meal, the by-product in processing hulled citrus seed for oil is rich in protein, having over 30 per cent. Florida tests show that it is a satisfactory protein supplement for cattle, but that it is poisonous to poultry and does not give good results when used in swine rations.[219] When used as the protein supplement for fattening cattle, citrus seed meal containing 35 per cent protein was fully equal to cottonseed meal of low grade, having 36 per cent protein.

975. Garbage; processed garbage.—In the vicinity of some cities, garbage is used extensively for swine feeding. Generally the garbage is fed by contractors who purchase the collected garbage from the cities or else collect it themselves under rigid rules. To prevent the spread of disease, the cooking or sterilization of garbage is now required by law in practically all our states.

Garbage varies greatly in composition and feeding value, but on an average and allowing for normal losses of hogs by death, a ton of city garbage may be expected to produce 35 to 40 lbs. of marketable live weight of hog, deducting the pork made from any feed supplied in addition to the garbage.[220] Garbage of excellent quality, such as that from large hotels and restaurants, may be worth twice as much, or even more. In prosperous times city garbage has a considerably higher feeding value than during a depression. The garbage on farms can be well utilized by feeding it to swine or poultry.

Very often, swine are not fed grain or other feeds in addition to garbage at gar-

bage-feeding plants, because garbage is so much cheaper. To prevent rickets, it may be necessary to feed some field-cured alfalfa hay or a vitamin D supplement.

Hogs fattened exclusively on garbage shrink rather more than grain-fed hogs on shipment to market, have a slightly lower dressing percentage, and may yield pork that is somewhat soft. It is also of interest that the lean meat of garbage-fed hogs is lower in thiamine content than that from grain-fed hogs.

Sometimes city garbage is processed and dried to produce *processed garbage* and to recover some of the fat for industrial uses. This product, also called "garbage tankage" or "table scrap meal," is much different from digester tankage or meat scrap, as it has only 17 to 23 per cent protein.

Processed garbage is not a satisfactory substitute for fresh garbage, apparently because of unpalatability.[221] It can be used to replace part of the tankage or fish meal in swine rations, but does not give good results when used as the only protein supplement for young pigs, even when they are on good pasture.[222] Processed garbage was not satisfactory as the only protein supplement for fattening lambs in Indiana tests, but the results were fair when equal parts of digester tankage and garbage tankage were used.[223] In Hawaiian tests dairy cows ate a mixture containing 25 per cent processed garbage satisfactorily, and chicks grew well when 20 to 30 per cent of processed garbage was included in a ration that also contained better protein supplements.[224]

976. Incubator waste eggs.—Incubator waste, consisting of infertile eggs and eggs that fail to produce live chicks, can be used for feeding swine and poultry. In Delaware and New York tests pigs gained satisfactorily on waste incubator eggs and corn.[225] On the average, 100 lbs. of the eggs replaced 17 lbs. corn and 21 lbs. of a trio-type protein supplement.

A considerable amount of raw egg white in the ration produces a nutritional deficiency disease in some animals, including pigs. This is because a compound in the raw egg white makes biotin (one of the B-complex vitamins) unavailable.[226] This compound is destroyed by cooking. However, in the Delaware and New York tests, there was no such trouble when pigs were fed raw incubator waste eggs.

Experiments have shown that incubator waste that has either been boiled and run through a food chopper or been dried, is a good addition to a ration for chicks.[227] The incubator waste should be heated high enough to kill any disease germs.

977. Kelp; other seaweed.—Dried kelp and also proprietary mixtures consisting chiefly of dried kelp, or kelp meal, are sold as supplements for livestock. Dried kelp, or kelp meal, is prepared from giant seaweeds, called kelp. It contains over 30 per cent of mineral matter, including 0.15 to 0.20 per cent of iodine and also various other minerals.

Several experiments have been conducted by various experiment stations to find whether or not there is a benefit from adding kelp to the usual type of well-balanced rations for various classes of livestock.[228] Similar experiments have been conducted with Manamar, a proprietary mixture consisting chiefly of dried kelp and fish meal.[229]

After considering the results of these various tests, it is the opinion of the author that it has not been proved in scientific investigations by the experiment stations that rations containing kelp will generally produce results that are superior to those that can be obtained on rations that contain no kelp, which have no lack of iodine or the other essential minerals, and which provide sufficient protein and protein of proper quality.

In the coastal areas of some countries other kinds of seaweed are sometimes used as a partial substitute for other roughage, especially for cattle or sheep. Also, some dried *seaweed meal* is made from certain species of seaweed. In an English test, when used as 10 per cent of the concentrate mixture for dairy cows, seaweed meal was of low palatability and was rated as having a value equal only to a mixture of 7 parts of oat feed (oat-mill by-product) and 1 part of common salt.[230] In a Canadian experiment the addition of 2 to 6 per cent of dried seaweed meal to a ration for bacon pigs did not increase the gain or improve the carcass quality.[231] In another Canadian trial dried seaweed meals from two species of seaweed were poorly digested by hens.[232]

978. Olive pulp.—Olive pulp, the by-product in expressing oil from olives, has a very low feeding value if it contains the pits, for they form about 40 per cent of such pulp. In an Italian test olive pulp was worth only one-third as much as corn when it formed 30 per cent of the concentrate mixture for dairy cows.[233] In California trials including 20 to 23 per cent of ground dried olive pulp, including the pits, in a ration for pigs reduced the gains and it took 4 lbs. of the olive pulp to equal 1 lb. of other feed.[234] No

better results were secured with olive pulp without pits.

979. Pear by-products.—*Dried pear pomace,* containing 13 per cent fiber, was equal to dried beet pulp for dairy cows in an Oregon trial when forming one-quarter of the concentrate mixture.[235] In a California trial with fattening steers *dried pear pulp* containing 31 per cent fiber, was worth only 70 to 75 per cent as much as dried molasses-beet pulp, when fed as one-quarter of the concentrate mixture.[236]

In this experiment *pear molasses,* fed at the same level, was fully equal to cane molasses.

In a Washington trial silage made from a mixture of 3 to 4 parts of pear waste and 1 part pasture clippings was a fair substitute for grass silage in feeding dairy cows, but it furnished considerably less digestible nutrients.[237]

980. Pineapple bran, or pulp.—Pineapple bran, or pulp, is a by-product from the canning of pineapples. It consists principally of the outer shells and usually the cores. Pineapple bran is occasionally fed wet, but is usually dried, molasses sometimes being added.

Pineapple bran resembles dried beet pulp in composition, except that it contains very little protein and this is poorly digested. Also, the content of total digestible nutrients is slightly lower than in dried beet pulp.

Pineapple bran is a popular dairy feed in Hawaii and considerable amounts are shipped to the Pacific Coast states. In Hawaiian experiments good results were secured when it formed one-third to two-thirds of the concentrate mixture for dairy cows.[238] It was also satisfactory for work mules when forming half of the concentrates, and for pigs when used as 30 to 50 per cent of the concentrates. Sometimes pineapple bran is soaked before feeding and used as a substitute for silage in dairy rations. The wet or dry pineapple bran has also given good results when fed to fattening cattle in Hawaii.

981. Potato meal; potato pulp.—Cull or surplus potatoes can be dehydrated, or dried, to make *potato meal.* This is a satisfactory substitute for grain in feeding cattle or sheep, and if the potatoes are heated sufficiently in the drying process to cook them thoroughly, a limited amount of potato meal can be used in swine or poultry rations. It must be remembered that potatoes are low in protein and deficient in carotene and calcium. These lacks must be made good by other feeds.

Potato meal has been equal to grain when forming 20 to 25 per cent of the concentrate mixture for dairy cows.[239] In an English test it was satisfactory when it was fed as 61 per cent of the mixture, with oil cake making up the remainder.[240] It was also equal to grain as a substitute for part of it in Arizona, Colorado, and Nebraska trials with fattening cattle or lambs, but in an Idaho test air-dried potatoes did not give good results with fattening lambs.[241]

Dehydrated Potatoes

Dehydrated potatoes, or potato meal, can be substituted for part of the grain in feeding livestock. (From Connell, Colorado Station.)

The results with potato meal for swine and poultry have differed greatly, probably depending on how much the potatoes were heated in the drying process.[242] In some tests the results were good when potato meal formed 10 per cent of the ration for young pigs, 30 per cent for older pigs, and 10 to 20 per cent for poultry. In other trials potato meal has been unsatisfactory for pigs or chickens.

Dried potato pulp, or potato pomace, is the by-product in starch production from potatoes. It is slightly higher than potato meal in total digestible nutrients, but is low in protein. If lime is added in the drying process, the calcium content will be high.

In Maine trials dried potato pulp was palatable to dairy cows and was nearly equal to hominy feed when forming 20 per cent of the concentrate mixture.[243] It was unsatisfactory for chicks or growing chickens in Maine tests, even when only 5 to 10 per cent was included in the ration.[244]

982. Raisins and other dried fruits; grape pomace.—*Cull raisins* may be fed to

stock as a partial substitute for grain. They were worth 82 per cent as much as barley in a California test when replacing one-third the barley in a ration for fattening lambs.[245] Pigs also produced satisfactory gains when cull raisins replaced up to one-half the grain in a ration, but the value of the raisins was less than for lambs. In another California trial raisins were fully equal to grain when forming as much as 16 per cent of the ration for growing turkeys.[246]

Cull dried apples, figs, pears or prunes can similarly be used for feeding.[247]

Raisin pulp, a by-product in the production of seeded raisins or in the manufacture of syrup from raisins, is of much lower value than cull raisins, for much of it consists of stems and seeds. For fattening lambs it was worth only 59 per cent as much as barley in California tests, when replacing part of the grain.[248]

Grape pomace, or winery pomace, the refuse in the production of grape juice or wine, consists chiefly of the grape seeds and skins. It is of such low value, even when ground, that it should not be used for feeding. In California digestion trials it supplied less digestible nutrients than straw, and in a New York test it had no value whatsoever for pigs, when replacing part of the grain in a ration.[249]

982a. Sewage sludge.—The dried residue from septic-tank disposal of sewage is used for fertilizer. It has nitrogen equivalent to about 30 per cent of protein, much of which is non-protein nitrogen. It is very high in mineral matter, having about 40 per cent. In recent Illinois studies with steers it was found that they would readily eat 1 lb. per head daily of dried sewage sludge when it was mixed with palatable feeds, but with full-fed fattening steers the palatability of the ration and the gains were reduced when sewage sludge replaced part of the soybean oil meal.[250]

The nitrogen of the sludge was less digestible and not utilized so well as that in soybean oil meal. Some manner in which this material can be successfully used for feeding ruminants may be found in further studies.

In Illinois tests with baby pigs fed a purified synthetic milk, 4 to 5 per cent of dried activated sewage sludge was an adequate source of vitamin B_{12}. A larger percentage of the sewage sludge decreased growth.[251] In a similar test with chicks 2 or 10 per cent of sewage sludge was a satisfactory vitamin B_{12} supplement.

983. Sweet potato meal.—In the southern states many experiments have been conducted to determine the value of sweet potato meal, or dried sweet potatoes, for stock feeding. This is because sweet potatoes yield more dry matter and a greater feeding value per acre there than does corn or any other cereal. However, the cost per acre of growing sweet potatoes is considerably higher than for corn, because of the large amount of labor required, and the cost of dehydrating them is rather high.

Sweet potato meal is usually made from cull or surplus sweet potatoes. The sweet potatoes are usually dried at dehydrating plants. Where the climate is suitable, they can be dried outdoors by spreading them, after being shredded or sliced in a machine, upon a suitable hard surface.

Sweet potato meal is even richer than corn in nitrogen-free extract (chiefly starch) and is low in fiber. It is therefore nearly equal to corn in content of total digestible nutrients.[252] It is very low in protein, calcium, and phosphorus. Care must be taken to correct these lacks when a large allowance is fed. Sweet potato meal is fully as rich as well-cured alfalfa hay in carotene, if made from a variety with good yellow color. If made largely from peelings or trimmings, the value of sweet potato meal is decidedly lower.

Sweet potato meal is a good substitute for grain in feeding dairy cattle, beef cattle, and sheep. It is not liked well by horses or mules and had best not form more than one-half of the concentrate mixture. It is least useful for swine or poultry.

Several experiments have been conducted to compare sweet potato meal with ground corn or other grain as a carbohydrate-rich feed for dairy cows.[253] In some tests it has been equal to ground corn, when replacing a considerable part of the grain in a concentrate mixture. In other trials dried sweet potatoes have been worth 88 to 95 per cent as much as corn. Because of their high carotene content, dried sweet potatoes increase the vitamin A value and the yellow color of milk. In most of the experiments sweet potato meal has been equal or nearly equal to corn when forming up to 30 or 50 per cent of the concentrate mixture. The value has usually been somewhat less when it has replaced all the corn or other grain.

When replacing not over half the grain for fattening cattle sweet potato meal has generally been worth 95 to 100 per cent as much as corn, but may have a lower value when it replaces all the grain, as it

is less palatable than grain and is somewhat laxative.[254] In Georgia trials dried sweet potatoes were an excellent concentrate for wintering pregnant ewes, as the ewes thus fed tended to produce more milk after lambing.[255]

The results have differed greatly in experiments in which dried sweet potatoes have been fed to swine.[256] Fairly good results are usually secured when dried sweet potatoes replace not more than one-fourth the grain. When a larger proportion is fed, the gains of pigs have often been very poor. Similarly, the results have differed decidedly when dried sweet potatoes have been used in poultry rations.[257] It therefore seems best to use them for other classes of stock.

984. Tomato pomace.—Dried tomato pomace is a dried mixture of tomato skins, pulp, and crushed seeds resulting from the manufacture of tomato juice or catsup. It has 22.9 per cent protein and 15.0 per cent fat, but is high in fiber, having 30.2 per cent. Tomato pomace is high in thiamine, is fair in riboflavin, and has considerable carotene. It is used chiefly in special feeds, such as dog foods.

In Delaware tests dried tomato pomace was satisfactory for dairy cows when forming 15 per cent of the concentrate mixture, and wet tomato pomace was a good addition to a ration for pigs.[258]

QUESTIONS

1. What is the composition of cow's milk? To what extent is whole cow's milk used in stock feeding?
2. Compare the composition of skimmilk and whole milk.
3. Why should dairy by-products be pasteurized at the dairy plant before being brought back to the farm?
4. Compare the composition of buttermilk and skimmilk.
5. Discuss the use and value of skimmilk and buttermilk for swine. How should they be fed to have the greatest value?
6. What is the approximate value of 100 lbs. of skimmilk for swine in terms of tankage and corn?
7. Discuss the use of skimmilk and buttermilk for poultry.
8. Compare the composition of whey and skimmilk.
9. Discuss the use of whey for: (a) Dairy calves; (b) swine; (c) poultry.
10. Discuss the use of the following in stock feeding: (a) Dried skimmilk and dried buttermilk; (b) condensed buttermilk; (c) dried whey.
11. Describe the two methods used in processing meat by-products.
12. What is the approximate protein content of the most important grades of digester tankage and of meat scrap?
13. What is rendering-plant tankage, or reduction tankage?
14. Discuss the use and value of tankage and meat scrap for: (a) Swine; (b) poultry; (c) dairy cattle; (d) beef cattle; (e) sheep; (f) horses.
15. For what purpose is blood meal chiefly used in stock feeding?
16. What is the composition of fish meal? What are the chief types of fish meal?
17. Discuss the use and value of fish meal for: (a) Swine; (b) poultry; (c) other classes of stock.
18. Are any other meat or fish by-products used for stock feeding in your region?
19. Discuss the composition and nutritive value of: (a) Cane molasses; (b) beet molasses.
20. Discuss the use and value of cane and beet molasses for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry.
21. Discuss the use and value of any of the following that are important in your region: (a) Dried beet pulp and dried molasses-beet pulp; (b) wet beet pulp; (c) molasses feeds; (d) alfalfa-molasses feeds.
22. Compare the composition and value of corn distillers dried grains and rye distillers dried grains; of distillers dried grains with solubles and without solubles.
23. Discuss the use and value of distillers dried grains for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) swine; (e) poultry.
24. What is the special value of distillers dried solubles?
25. For what purpose is dried yeast chiefly used in stock feeding?
26. How should a farmer decide whether to buy a commercial mixed feed or to prepare a suitable mixture on the farm?
27. What is meant by open formulas and closed formulas for commercial mixed feeds? What are the advantages of each?
28. Tell how you would prepare a concentrate mixture on the farm.
29. What are premixes?

30. Discuss the use of antibiotic feed supplements.
31. For what classes of stock are arsonic supplements used?
32. What is your opinion concerning the use of complex mineral or vitamin supplements?
33. Discuss the use of stock tonics.
34. Discuss the use and value of any of the feeds considered in Articles 969 to 984, which are assigned by your instructor.

CHAPTER XXIV

MANURIAL VALUE OF FEEDING STUFFS

985. Importance of manure in maintaining fertility.—One of the great advantages of livestock farming is that the use of farm manure makes possible the maintaining and building up of soil fertility at minimum expense. Unless the plant food removed by the growth of crops is returned in some form, the land will sooner or later become so poor that profitable crops cannot be grown.

When proper use is made of farm manure, most of the plant food contained in the crops fed to stock is returned to the fields. If, in addition, legumes are grown regularly in the crop rotation to help in supplying nitrogen, the soil fertility can then be built up with but minimum use of commercial fertilizers.

986. Farm manure as a fertilizer.—Farm manure, like commercial fertilizers, is valued chiefly on the basis of the nitrogen, phosphorus, and potassium it contains. These fertilizing constituents and calcium are the only plant foods that ordinarily need be replaced of those which are removed from the soil by crops.

In addition to the amounts of plant food it furnishes, farm manure also has other beneficial effects. The large quantities of organic matter it contains add to the humus content of the soil, thus increasing its water-holding capacity, improving the texture, and making it more resistant to wind action. In the decay of the organic matter, acids are formed that help to dissolve plant food in the soil that would otherwise be insoluble. A good supply of organic matter in the soil is so important that when farm manure is not available, special green manuring crops are often grown and plowed under, solely to furnish organic matter.

Manure also has a beneficial effect because of the great numbers of various kinds of bacteria that it contains. These cause chemical changes not only in the manure but also in the soil itself, changing insoluble plant food into forms available to crops.

Experiments have shown that the fertilizing constituents present in manure when it is applied to the land have fully as high a value as those in high-grade commercial fertilizers. The cost of nitrogen, phosphorus, and potassium in commercial fertilizers varies considerably, depending on the type of fertilizer and the section of the country. In this chapter the following prices are used in computing the fertilizing values of feeds and farm manures: Nitrogen, 15 cents per pound; phosphoric acid, 10 cents per pound; and potash, 5 cents per pound.

The amount of phosphorus in a commercial fertilizer is commonly expressed in terms of *phosphoric acid* (P_2O_5), instead of *phosphorus* (P). On the other hand, in animal nutrition and livestock feeding, the amount of the mineral is now generally expressed as *phosphorus*. Similarly, the amount of potassium in fertilizers is usually expressed in terms of *potash* (K_2O), instead of *potassium* (K).

The preceding prices for phosphoric acid and potash are equivalent to 22.9 cents per pound for phosphorus and 6.0 cents per pound for potassium.

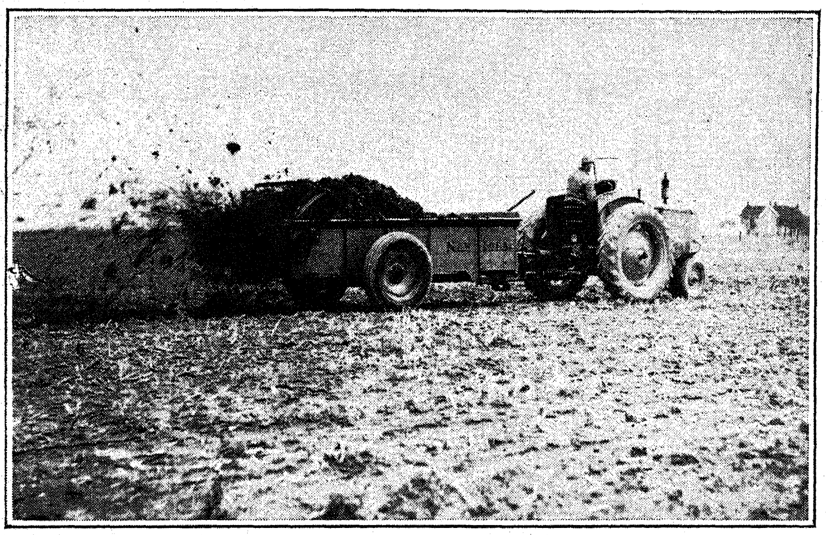
987. Fertilizing constituents recovered in manure.—The fertilizing constituents in manure come entirely from the feed consumed, for an animal creates no fertility value. It merely excretes in the feces and urine a greater or less percentage of the nitrogen, phosphorus, and potassium that is contained in the feed it eats. The value of the manure therefore depends, first of all, on the kind of feed the animal gets. Only feeds rich in fertilizing constituents make rich manure.

The proportion recovered in the manure of the fertilizing constituents that the feed contains, depends on the age

kind of animal. A mature animal (such as a work horse) which is not gaining in weight and which is not pregnant or producing milk, will excrete in feces and urine all the fertilizing constituents in its feed, with the exception of the nitrogen used in the growth of hair or wool and the small amounts of fertilizing constituents contained in the sweat. Therefore such an animal will excrete in feces and urine practically all the nitrogen, phosphorus, and potassium there is in its ration.

On the other hand, a young growing animal in building its body will store a considerable proportion of the fertilizing constituents there are in its feed. A calf a few weeks old may store fully two-thirds of the nitrogen and mineral matter there are in the milk and other feed it consumes. As an animal grows older, the proportion of the nitrogen and mineral matter that is stored in growth rapidly decreases, and the proportion excreted in the manure correspondingly increases. Thus, 5-month-old calves will excrete in the manure about 70 to 80 per cent of the nitrogen in their feed, and 2-year-old fattening steers about 87 per cent.[1]

Because of the richness of milk in nitrogen and in phosphorus, when dairy cows producing a good yield of milk are fed the usual types of rations they will excrete in feces and urine only about 70 per cent of the nitrogen in their ration and 63 per cent of the phosphorus.[2] The proportion of potassium is considerably higher, being about 86 per cent.



Saving the Fertility in Feeding Stuffs

If possible, the manure should be drawn directly to the field and spread each day. However, this is not advisable on sloping land in winter when there is deep snow on the fields. (From New Idea Farm Equipment Company.)

Considering the proportion of the various classes and ages of animals on the average general farm, probably about 80 per cent of the fertilizing value of all the feed consumed is excreted in the feces and urine. On dairy farms, where most of the animals are cows in milk, the percentage will be somewhat lower.

988. Fertility and manurial value of feeds.—In buying or selling feeds, too few farmers consider their value as fertilizers as well as the feeding value. The amounts of fertilizing constituents in the important feeds are given in Appendix Table I. To bring out certain points, there are presented in the following table

these data for a few typical feeds and also data for certain animal products. The fertility value of each has been computed at the prices for nitrogen, phosphorus, and potassium given previously.

The last column gives the average manurial value of the various feeds. This has been computed on the assumption that when proper care is taken of the manure, there can be recovered in the manure for application on the land an average of 70 per cent of the phosphorus and potassium and 50 per cent of the nitrogen contained in the feed. These estimates take into consideration the fact that some losses of fertilizing constituents, especially of nitrogen, occur in the storage and application of manure, even when the precautions are taken which are mentioned later. Obviously, these manurial values hold good only when the manure is handled properly.

The table shows that the fertility value of corn grain is $5.76 per ton. This means that the nitrogen, phosphorus, and potassium removed from the soil in [illegible] ton of corn would cost about $5.[illegible] if bought in commercial fertilizers. The manurial value of corn grain is $3.20 per ton, which means that the manure resulting from feeding a ton of the grain to stock will, on the average, supply about $3.20 worth of fertilizing constituents, if proper care is taken of the manure.

Fertilizing constituents in feeds and in animal products

	Fertilizing constituents			Fertility value per ton	Manurial value per ton
	Nitrogen	Phosphorus	Potassium		
	Per cent	Per cent	Per cent	Dollars	Dollars
Concentrates					
Corn, dent, No. 2	1.39	0.27	0.29	5.76	3.20
Oats	1.92	0.33	0.43	7.79	4.[illegible]
Barley	2.03	0.40	0.49	8.51	4.74
Wheat bran	2.62	1.29	1.23	15.24	9.10
Soybeans	6.06	0.59	1.50	22.68	12.24
Linseed meal	5.63	0.86	1.24	22.32	12.24
Cottonseed meal, 41% protein	6.66	1.11	1.48	26.84	14.79
Tankage, digester, 60% protein	9.50	3.23	0.46	43.85	24.99
Roughages					
Alfalfa hay	2.45	0.24	1.97	10.81	6.10
Clover hay, red	1.92	0.20	1.65	8.66	4.91
Timothy hay	1.06	0.14	1.59	5.73	3.38
Oat straw	0.66	0.09	2.00	4.79	2.96
Corn silage, well matured	0.37	0.07	0.30	1.79	1.03
Animal products					
Fat steer	2.56	0.59	0.14	10.55	....
Fat pig	2.32	0.37	0.13	8.81	....
Milk	0.56	0.10	0.14	2.31	....
Butter	0.14	0.02	0.01	0.52	....

The fertility values and the manurial values are somewhat higher for oats and barley than for corn, because these grains contain more nitrogen, phosphorus, and potassium than does corn. The values for the protein-rich feeds, such as soybeans, linseed meal, cottonseed meal, and tankage, are high, because of their richness in nitrogen and also in minerals. If legume crops, such as soybeans, are properly inoculated, the amount of fertility removed from the soil is much less than indicated by the fertility value of the crop. This is because most of the nitrogen will have been secured indirectly from the air, instead of from the soil.

When such protein-rich feeds as cottonseed meal, linseed meal, and tankage are purchased and fed to stock and proper care is taken of the manure produced, a double return is secured. The first return comes from the high feeding value of these protein supplements, and the second comes from the fertility added to the soil.

The fertility value of legume hay is much greater than that of grass hay, because of its richness in protein. It is important to note that when the hay is fed to stock and proper care is taken of the manure, each ton of red clover hay will add [illegible] worth of plant food to the soil and each ton of alfalfa hay, $6.10.

989. Selling fertility.—The preceding table also shows that farmers who sell such crops as hay, corn, and wheat, part with more fertility for a given sum than do those who sell animals or their produce. The farmer who sells 1,000 lbs. of clover hay, worth $10 to $12, parts with about as much fertility as if he had sold 1,000 lbs. of fat cattle or pigs, worth 10 to 20 times as much. Based on the selling price, milk carries considerable fertility from the farm and butter practically none.

The farmer who grows and sells grain, hay, and straw is selling a large amount of fertility, the need of which will surely be apparent as time goes on and his fields give smaller and smaller returns. Such a farmer is slowly but surely mining phosphorus and potassium from his soil, which can be replaced only by some purchased material.

In Great Britain, where many of the farmers are long-period tenants, the manurial value of feeding stuffs is recognized by law. When a tenant vacates his leasehold, he is paid for the manurial value of feeds which he has recently purchased and fed on the farm, and, under certain conditions, for the manurial value of grain produced on the farm and fed to stock. Similar provisions should be drafted into farm leases in this country.

990. Buying fertility in purchased feeds.—Even in livestock farming where little or no grain or roughage is sold and when proper care is taken of the manure, not all of the fertility in the crops is returned in the manure. The growth of legumes will aid in maintaining the nitrogen supply in the soil, but under actual conditions on most farms, supplying additional nitrogen in manure or fertilizer will increase crop yields.

Sooner or later in practically all cases it is necessary to replace the small but steady loss of phosphorus and potassium. In purchasing feeds, one should therefore consider not only their feeding value but also their worth as fertilizers. By a wise selection of purchased concentrates, the livestock farmer can build up the fertility of his farm without the use of any commercial fertilizers, except lime to correct soil acidity and probably phosphate to balance the farm manure, which is ordinarily much richer in nitrogen than in phosphorus.

To determine which feeds are the cheapest when consideration is given to the manurial value, one should deduct the manurial value per ton from the gross price.

For instance, in an example given in Chapter X of the method for determining which feeds are the cheapest sources of total digestible nutrients and of digestible protein, it was assumed that a dairyman had ground corn available on the farm at a price of $52.00 per ton. (388) Among the protein supplements he could purchase on his local market was cottonseed meal (41 per cent protein grade) at $70.00 per ton.

If we deduct the manurial value of cottonseed meal per ton (which is $14.79) from the purchase price the net cost per ton would be only $55.21 per ton. Similarly, deducting the manurial value of corn ($3.20 per ton) from the price, the net cost would be $48.80 per ton. Thus, at these prices the net cost of cottonseed meal is only $6.41 more per ton than that of corn, if proper credit is given for the difference in the manurial values of the two feeds.

991. Composition and value of fresh manure.—The value of farm manure produced by animals of the same kind varies rather widely, depending chiefly on the nature of the feed sup-

plied. However, it is desirable to have an approximate idea of its general composition.

Mixed fresh farm manure from dairy farms, including bedding, contains an average of 10 to 12 lbs. of nitrogen, 5 lbs. of phosphoric acid (equivalent to 2.2 lbs. of phosphorus), and 10 lbs. of potash (equivalent to 8.3 lbs. of potassium) per ton. With these fertilizing constituents at the prices stated previously, average farm manure has a value of $2.50 to $2.80 per ton.

The average composition of fresh manure (including bedding, except in the case of hen manure) for the various classes of farm stock is shown in the following table.[3] The last column shows the average value per ton of the various kinds of manure. The table also shows the composition of dry floor-litter hen manure, as accumulated in a laying house.

Average composition of manure from farm animals

	Water Per cent	Nitrogen Lbs. per ton	Phosphorus Lbs. per ton	Potassium Lbs. per ton	Value Dollars per ton
Dairy cows	79	10.7	2.1	9.4	2.65
Fattening cattle	78	14.6	4.2	9.2	3.70
Sheep	64	21.5	6.3	22.0	5.99
Horses	59	14.0	2.2	12.8	3.37
Swine	74	9.8	3.0	7.8	2.63
Hens (without litter)	76	22.6	7.6	7.6	5.59
Hens (dry floor-litter manure)	25	45.2	22.8	20.4	13.23

The manure from horses, sheep, and hens is much drier than that from cattle or swine, and therefore is especially apt to heat unduly in storage, on account of rapid fermentation. These manures are often called "hot manures," in contrast to manures from cattle and swine, which are termed "cold manures."

992. Manure produced yearly.— The amount of manure (including bedding) produced yearly by any class of stock will vary considerably, depending chiefly on the liberality of feeding and the amount of bedding. When all the manure is saved, approximately the following amounts of manure, including bedding, are produced per 1,000 lbs. live weight by the various classes of stock:[4] Dairy cows, 15 tons; fattening cattle, 8.5 tons; sheep, 7.5 tons; horses, 9 tons; swine, 18 tons; and poultry, only [illegible] tons.

Under usual farm conditions much of the manure is not voided in the stable. That which is excreted by stock on pasture or by horses working in the fields is commonly well utilized, but a considerable loss occurs through the amounts voided in exercise paddocks or by horses on the road.

In Ohio studies it was estimated that the following amounts of manure, ready for field application, were produced *per head* by farm animals in a year, excluding that voided while the animals were in the yards or at work:[5] Horses, 6.0 tons; fattening cattle, 7.8 tons; sheep, 0.75 ton; and hogs, 1.7 tons.

In studies on Illinois dairy farms it was found that 6.6 loads of manure (including bedding) were actually recovered annually per mature cattle unit.[6] For work horses and mules the amount actually hauled to the fields was 5.45 loads per head annually.

In other Illinois studies when beef cattle were fattened in paved feed lots with adjacent sheds, the amount of manure recovered per head was 0.23 to 0.30 ton per month for fattening calves and 0.45 to 0.51 ton per month for yearlings.[7]

993. Importance of saving urine.— In preventing losses of fertilizing value in farm manure, one of the most important points is to use sufficient bedding to absorb the urine. In the case of cattle and sheep, the urine may contain fully one-half of the nitrogen in the total excrement and three-fourths of the potassium.[8] Even for horses and swine, one-third of the nitrogen and two-fifths of the potassium are in the urine. Practically

all of the phosphorus and calcium is in the feces except in the case of swine, which excrete about 12 per cent of the phosphorus in the urine.

Pound for pound, the urine has a greater fertilizing value than the feces, except with swine, whose urine is large in quantity, and watery. The fertilizing constituents in the urine are also in solution, hence much more readily available to plants than those in the feces. The feces consist chiefly of food residues which were too insoluble to be digested.

It is obvious that much fertility is lost if the urine drains away from the stable, because of insufficient bedding and gutters that are not water-tight. Also, there is usually a heavy loss of fertility in exercise paddocks.

994. Bedding, or litter.—Bedding, or litter, not only keeps stabled animals clean and comfortable, but it is also very important to absorb the urine. In addition, it increases the content of organic matter, it may supply significant amounts of plant food, and it makes the manure easier to handle.

Straw is the most common bedding material on most stock farms. If it is not too coarse, straw will absorb 2 to 3 times its weight of water, or even more.[9] Unless straw is very coarse, as is the case with rye straw, chopping does not increase its water absorbing capacity very much. For bedding dairy cows, it may require a larger weight of cut straw than of long straw, as the latter stays in place better.[10] The amounts of fertilizing constituents in various kinds of straw are shown in Appendix Table I.

From 4 to 8 lbs. of straw per head daily are usually sufficient for dairy cows in stanchions, if the platforms are of the proper length. Considerably more is needed when cows are housed in a loose stable. (1089) In Illinois tests 4 to 5 lbs. per head daily of straw were needed for 1,000-lb. fattening steers which were fed in open sheds that were cleaned once a month.[11] Twice as much was needed when cattle were kept in single stalls that were well-bedded and cleaned once a day.

When stock are fed *shredded* or *cut dry corn* or *sorghum stover* or *fodder*, the coarser parts that are refused make satisfactory bedding. If not needed for feed, finely-shredded stover makes excellent bedding, nearly equalling straw in water-absorbing capacity.

When these farm-produced bedding materials are not available, either *wood shavings* or *sawdust* are used most commonly as the substitute. These wood by-products, especially from hardwood, often have a somewhat lower absorptive capacity per pound than straw. Shavings and sawdust add very little fertility to manure, and they do not decompose rapidly in the soil. A much greater weight of shavings is required than of straw for bedding dairy cows. In Indiana tests more than twice the weight of shavings was needed.[12]

When manure contains a large amount of sawdust or shavings, or even of straw, in proportion to the amount of excrement, a temporary deficiency of available nitrogen may be produced in the soil. This is because much of the nitrogen in the manure is assimilated by soil bacteria in the decomposition of the material, and then converted into forms that are only slowly available to plants. This effect can be prevented by supplementing such manure with a readily-available nitrogen fertilizer. Except for this effect, the use of any ordinary amount of sawdust or shavings for bedding is not detrimental to crops.[13]

Portable machines have recently been developed by means of which waste limb wood or brush is chipped fine enough for bedding. Chipped wood was satisfactory bedding for dairy cows in Indiana and New York tests, but a greater weight was needed than of shavings.[14]

Ground corn cobs, ground in a hammer mill with a five-eighths inch screen, were satisfactory bedding for dairy cows in Indiana tests.[15] It required over 3 times the weight of ground cobs as of straw.

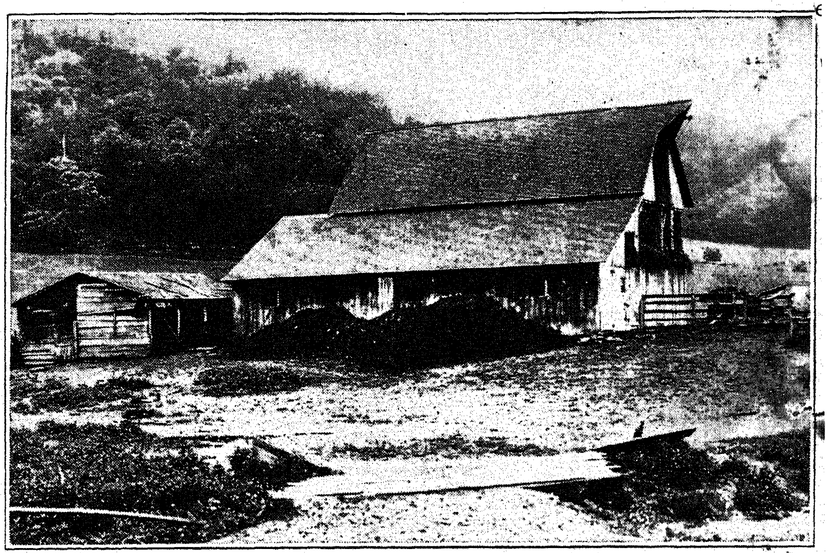
Dry *peat moss* absorbs 5 to 10 times its weight in water, is a good deodorant, and is excellent for bedding, but it is usually expensive. It is especially good

for calf pens. Cows may become stained if the same peat moss is used in the stall too long. Contrary to claims sometimes made, peat had no inhibiting effect on the development of flies in the manure in tests by the United States Department of Agriculture.[15]

Cocoa shells are sometimes used for bedding and have about the same absorbing capacity as straw.[16] They are a good deodorant but are difficult to keep in place in dairy stables, and they pack hard.

Peanut hulls, or shells, are sometimes used for bedding. The unground hulls have about the same water-absorbing capacity as sawdust or shavings. However, in dairy stables, peanut hulls do not stay under the cows so well as shavings or straw.[17] They are also inclined to stick to the hair on the udders. In the production of sanitary milk, cows bedded with peanut hulls may therefore require more brushing than those bedded with straw or shavings. In the summer, peanut hulls may attract flies, because of small amounts of fragments of oily peanut kernels still left in the h

Buckwheat hulls have ab the same absorptive capacity as shavi but they are rather hard to keep in p for dairy-cow bedding.[18] They son es lodge between the toes of cattle, s- ing infection. It is not safe to bed s with buckwheat hulls, for they ofte t them, which is apt to cause ind ge



Such Losses of Fertility Occur on Many Farms

When manure is loosely piled under the eaves, heavy losses of fertility occur through fermentation and leaching. Note that every hard rain will leach fertility from the manure pile to the ditch in the foreground. (From Wisconsin Station.)

Oat hulls may likewise be used for bedding, but they have the same disadvantages as buckwheat hulls and are dusty for use in dairy stables. They are excellent, however, as poultry litter.

995. Reducing the losses in farm manure.—In spite of the value of farm manure, many farmers who freely purchase commercial fertilizers allow much of the value of the manure produced by their livestock to be wasted. Manure is a perishable product, and unless proper care is taken over half its value may be lost. The losses occur through: (1) Loss of urine; (2) loss by leaching; and (3) loss of nitrogen by fermentation.

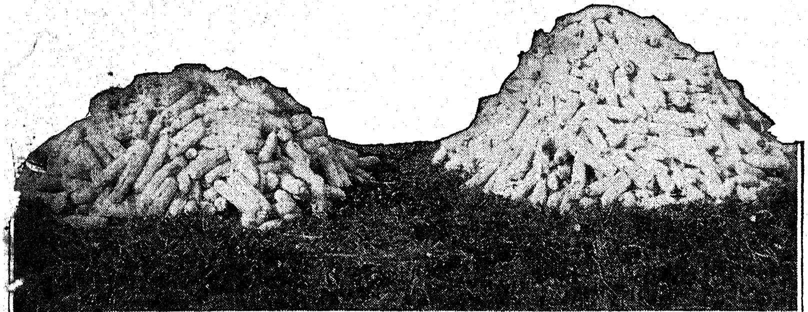
A manure pile against the side of the barn and under the eaves, or manure lying for months in an open barn yard, is a sight all too common. When manure is thus exposed to the leaching action of rains, the losses are great, even amounting to half of the total value in periods of 2 to 5 months. Unfortunately, the loss falls on the constituents which are most soluble and therefore most quickly available to plants.

When manure is stored, the mass must be well packed and kept damp, or hot fermentation will occur, in which a large part of the nitrogen may be lost. In this process there is a rapid formation of ammonia from the nitrogenous compounds, and much of this ammonia escapes as gas into the air. The strong smell which is very noticeable in unventilated horse stables is due to this escaping ammonia gas, produced by the breakdown of nitrogenous compounds in the urine. In still other changes which may take place, free nitrogen gas may be formed, which is likewise lost into the air.

When the pile of manure is well packed and is kept damp, these changes cannot go on, but only the decay which makes the plant food more available and produces what is termed "well-rotted manure." If the manure is very loose and dry, "fire fanging" may occur, the manure becoming grayish or dusty in appearance. This change, which is brought about by certain molds, causes serious losses of nitrogen. Phosphorus and potassium are not lost through fermentation, but heavy losses of these minerals may occur through leaching.

To reduce the losses of fertility in manure to the minimum, first of all, the urine should be saved by having tight gutters and using plenty of bedding. When possible, the manure should be drawn directly to the fields and spread each day. This is not advisable, however, in winter on very sloping land when covered by deep snow, as much fertility may wash down the hill in the spring. Even when the fresh manure is spread daily on the fields, a heavy loss of nitrogen may occur if it is not soon plowed under or disked under.

Adding superphosphate (acid phosphate) to the manure greatly decreases the losses of nitrogen, no matter whether it is spread at once or whether it is properly stored. Also, since manure is much richer in nitrogen than in phosphorus, the phosphorus fertilizer usually increases crop yields considerably. Caustic forms of lime, such as hydrated lime, increase the loss of nitrogen in the form of ammonia from manure that has fermented, but may be used daily in the gutter without detrimental effect.



THE RESULT OF ALLOWING MANURE TO WASTE AWAY

When manure is allowed to waste away as in the illustration on Page 570, not only is much of the weight of the manure lost, but that which remains contains much less fertility per ton than fresh manure. The pile of corn at the left was grown on a plot fertilized with manure which had been exposed to the weather over winter. The large pile at the right was grown on a plot fertilized with the same amount of fresh manure. (From Wisconsin Station.)

When manure cannot be spread at once on the land, it should be stored under cover, if possible, and in well-packed piles which are kept moist to prevent hot fermentation. The shed or pit should preferably have a concrete floor, to prevent any draining away of liquid. It is an excellent plan to mix the manure from horses, sheep, or poultry (which is drier), with the cattle or pig manure (which contains more water).

The value of manure is well preserved when a deep layer is allowed to accumulate in a well-bedded stable in which stock run loose. The layers of manure under the surface are thoroughly packed by the animals and are kept damp, so the loss of nitrogen is reduced to a minimum.

When it is necessary to leave manure outdoors, the pile should be built with the sides perpendicular and the top should be flat or sloping slightly toward the center, so that all rain will soak into the pile instead of draining off as from a stack of hay. It is impossible to prevent all waste when manure is stored, but under proper management not over 25 to 30 per cent of the nitrogen and practically none of the phosphorus and potassium will be lost.

In some European dairy districts large concrete tanks are used for holding the urine and solid feces, not including bedding. Here the contents can be stored without appreciable loss of nitrogen. The mixed contents are pumped into tanks, somewhat like a street sprinkler, and distributed on pasture fields grazed rotationally, after the stock have finished grazing a plot. This method is used to some extent in certain areas of this country, especially in the Pacific Northwest. It is very efficient in conserving fertility, but requires additional labor.[19]

QUESTIONS

1. How are the fertilizing values of feeding stuffs and of farm manures computed?
2. What beneficial effects does farm manure produce in the soil in addition to the plant food it supplies?
3. About what percentage of the fertilizing constituents in their feeds do mature work horses (not pregnant or nursing foals) void in the manure; young calves; dairy cows?
4. Give examples of feeds which are high and of others which are low in fertility value.
5. How is the manurial value of a feed computed?
6. A farmer who intends to fatten feeder steers has on his farm shelled corn, corn silage, and clover hay. To provide a well-balanced ration, he sells 10 tons of corn and buys as much cottonseed meal as he can with the proceeds. Using local market prices and assuming that the feeding value of the cottonseed meal is enough greater than that of the corn to pay for hauling, find the gain or loss in manurial value from the exchange.
7. Compare the fertility lost in selling a ton of corn; a ton of fat pigs; a ton of butter.
8. What are the average amounts of fertilizing constituents in a ton of mixed fresh farm manure?
9. Discuss the differences in composition and value of manure from horses, dairy cows, fattening cattle, sheep, swine, and poultry.
10. What are "hot manures" and "cold manures"?
11. About how much manure, including bedding, is produced per head annually by horses; by dairy cows; by sheep; by hogs?
12. Why is it important that the urine be saved?
13. What kinds of bedding are used for stock in your district?
14. Discuss the losses that occur in farm manure and tell how it should be handled to reduce the losses to a minimum.

PART III

FEEDING FARM ANIMALS

CHAPTER XXV

GENERAL PROBLEMS IN DAIRY HUSBANDRY

I. Factors Determining the Efficiency of Dairy Cows

996. Economy of food production by dairy cows.—It is highly important for the health and well-being of humans that they have an abundant supply of milk and other dairy products. This is because the great nutritive merits of milk put it in a class by itself as a human food. (**269**) Fortunately, dairy cows not only excel in the nutritive value of the food they produce for us, but they also excel in the economy with which they produce this unrivalled food.

It has been shown in Chapter XII that dairy cows even surpass swine, our most efficient meat producers, in the efficiency with which they convert the digestible nutrients in the feed they eat into energy in food for human beings. (**351–352**)

The chief nutritive merit of milk is not, however, the energy it furnishes, but the rich store of the nutrients that we need to make good the deficiencies in our cereal foods. We need milk's abundant supply of highest quality protein, its high vitamin A value, its content of other vitamins, its richness in calcium, and the especial value of the milk sugar in our diet. (**353**) Considering all these factors, the dairy cow may well be called "the foster mother of the human race," a title which was apparently first bestowed on her by W. D. Hoard of Wisconsin.

When we compare the economy of milk production by the dairy cow with meat production by beef cattle, sheep, or poultry, the efficiency of the cow is striking. For example, good dairy cows yield in their milk, per acre of crops eaten, over 5 times as much energy and nearly 4 times as much protein as is contained in the beef made by steers from the same amount of feed.[1]

997. High producers are economical producers.—One of the most important facts in dairying is that high-producing cows are almost always much more economical producers of milk and butterfat than are low producers. Also, the return over feed costs is much greater for high producers. These facts are well shown by the table on the next page. In this table data for cows completing records of production in dairy-herd-improvement associations during 1952, in this country, are grouped according to the level of production.[2]

For the dairyman, the most important fact shown by the table is that the return over feed cost steadily became greater as the yield of milk and fat increased. This was true even at extremely high levels of production. Also, the feed cost of producing 100 lbs. of milk was much less for high producers than for the low yielders.

While this fact is always extremely important, it is vital when the price received for milk is low in comparison with the cost of feed and labor. At such a time only the dairyman with high-producing cows stands any chance of securing a reasonable return over feed cost.

The table shows that as the production became greater, there was a steady increase in the cost of feed, but

the value of the product increased much more rapidly. For example, the cost of feed for the group averaging 13,953 lbs. milk and 501 lbs. fat was $69 more than for the second group, which averaged only 5,048 lbs. milk and 241 lbs. fat, but the value of the product was $345 greater. This made the return over feed cost nearly three times as great for the cows in the higher-producing group.

Relation of level of production to cost of feed and return above feed cost *

Milk production, range	Average yield of milk	Average yield of fat	Value of product	Cost of roughage including pasture	Cost of concentrates	Total cost of feed	Return above feed cost	Feed cost of 100 lbs. milk
Lbs.	Lbs.	Lbs.	Dollars	Dollars	Dollars	Dollars	Dollars	Dollars

18,500–19,499	18,941	673	837	96	156	252	585	1.33

* Based on the records of 50,005 DHIA cows, selected at random, that completed a full 12-month testing period in 1952. Cows producing less than 3,500 lbs. of milk and those yielding 19,500 lbs. and over are omitted in this table, because of the small numbers in these groups.

Fully as important is the fact that the feed cost per 100 lbs. milk was only $1.54 for the cows yielding 501 lbs. fat, while it was $2.89 for the group averaging 241 lbs. fat.

This table effectively disproves the statement, sometimes made, that greater net returns are secured from moderate rates of production than from the high levels of production reached by excellent cows fed in accordance with their nutrient requirements.

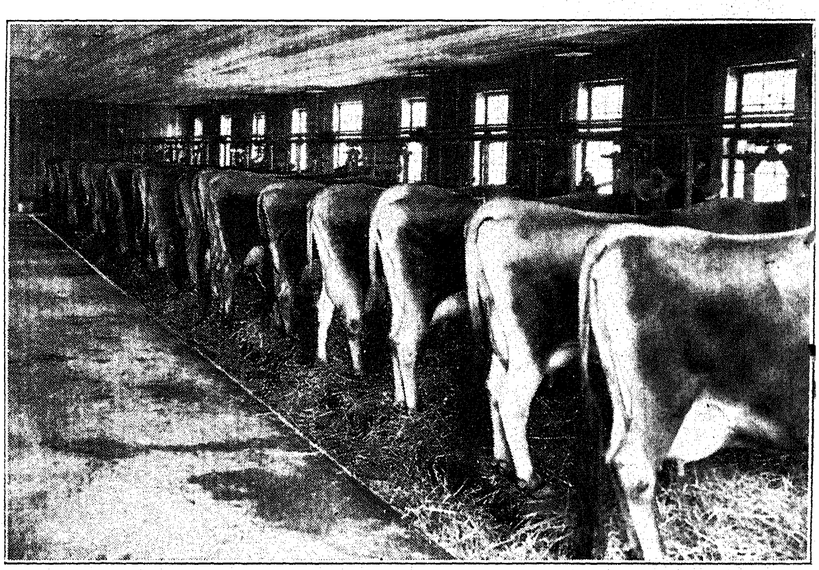
998. Why high producers are more efficient.—High producing cows are more efficient than low producers chiefly because of their great inherited capacity for milk production, combined with a strong constitution and the ability to consume and utilize a great amount of feed. They secrete a large yield of milk and, because of the great quantities of nutrients they put into their milk, they have keen appetites. If fed properly, they eat much more feed than low producers, and use this feed more efficiently for milk production. This is because they have left for milk production a much larger proportion of the feed nutrients, after their maintenance requirements are met. (**1001**)

Missouri experiments showed that high producers and low producers do not differ appreciably in the efficiency with which they digest their feed.[3] Opinions differ as to whether or not high producers require less feed than low producers merely to maintain their bodies. In the Missouri studies there was no difference in this respect between high and low producers. On the other hand, from statistical studies of the results of feeding experiments, Headley of the Nevada Station concluded that high producers required somewhat less nutrients than did

low producers for mere maintenance.[4] One factor causing the difference between high producers and low producers may be the size or rate of activity of the thyroid gland, which regulates the rate of metabolism in the body.[5] (54) Cows in warmer climates seem to have smaller thyroids than in our northern states.

While the chief difference in efficiency of milk production is between high producers and low producers, there may be some difference in efficiency between cows that yield the same amounts of milk and fat. For example, let us take two cows which both produce in a year 10,000 lbs. of milk containing 3.7 per cent fat, but one cow weighs 1,000 lbs., while the other weighs 1,400 lbs.

The larger cow will generally consume considerably more feed than the smaller cow, because she needs more nutrients to maintain her larger body. If she produces no more milk than the smaller cow, her efficiency will obviously be lower. To compare the real efficiency of various cows, we must therefore consider not only milk and fat yields but also live weight.



HIGH MILK PRODUCTION NECESSARY FOR EFFICIENCY

High-producing cows are almost always much more economical producers than are low producers. A high-producing herd of Jerseys.

999. Fat-corrected milk yields.—Milk containing the various percentages of fat differs widely in energy content per pound. Therefore to compare the actual amounts of milk energy produced by various cows, the yields must be equated, or changed, to a uniform energy basis. This is done by converting the various actual yields to equivalent amounts of milk of a uniform fat percentage, and therefore of the same energy content.

The usual method is to convert the yields, by the formula developed by Gaines of the Illinois Station, to amounts of "4 per cent fat-corrected milk" (commonly called merely "fat-corrected milk," and abbreviated to F.C.M.).[6] This is done by multiplying the actual milk yield by 0.4 and then adding to this product the actual fat yield multiplied by 15. In condensed form, the formula is:

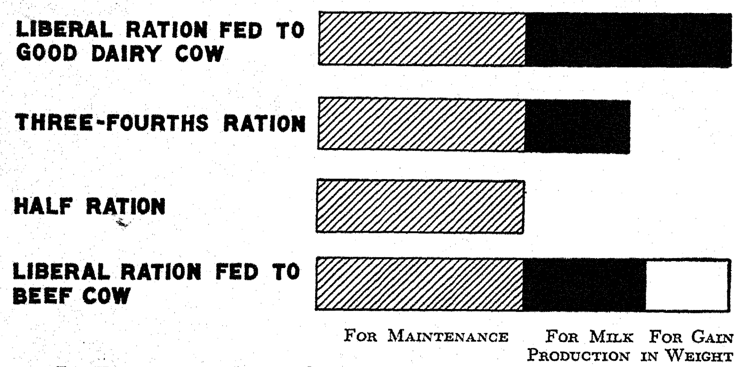
$$\text{F. C. M. (4 per cent fat-corrected milk)} = 0.4 \times \text{milk} + 15 \times \text{fat}.$$

If desired, the milk yields can be converted to some other uniform fat percentage than 4 per cent, by the use of a different formula.

To compare the production of heifers with that of mature cows, the actual yield is converted to a "mature equivalent basis" by multiplying the yield by an "age-correction factor." (1055)

1000. Measuring the efficiency of milk production.—The efficiency with which various cows produce milk can be compared by computing the energy content of the milk each has produced in a year and dividing this by the energy in the total digestible nutrients in the feed each has consumed. The quotient is called the *gross efficiency of milk production.*[7]

USE OF FEED BY COWS



IT PAYS, TO FEED GOOD DAIRY COWS LIBERALLY

When fed liberally a good dairy cow can use half her feed for milk production. When fed a three-fourths ration she can use only one-third of her feed for producing milk, and when fed a half-ration she needs all her feed to maintain her body. A beef cow, if fed a liberal ration, will turn part of her surplus feed into fat instead of milk.

Each pound of 4 per cent fat-corrected milk has approximately 340 Calories of energy, and each pound of total digestible nutrients supplies about 1,814 Calories. The formula for computing the gross efficiency of milk production is therefore:

$$\text{Gross efficiency} = \frac{340 \text{ Cal.} \times \text{lbs. of F.C.M.}}{1814 \text{ Cal.} \times \text{lbs. of T.D.N.}}$$

In computing the amount of total digestible nutrients consumed in a year, the amount the cow secures from pasturage must be estimated as closely as possible, since it may furnish the major part of the nutrients during the growing season.

Brody of the Missouri Station has compiled the records of production and feed consumption of 243 cows at various experiment stations.[7] These cows averaged 1,087 lbs. in weight and produced an average of 10,315 lbs. of 4 per cent fat-corrected milk a year. Their average gross efficiency of milk production was 30.1 per cent.

Various cows of the same live weight and productive capacity may differ somewhat in the efficiency with which they digest and utilize feed, but these differences are not generally large, if the cows are healthy. Brody has therefore prepared a detailed table which shows the estimated gross efficiency of cows of various live weights and producing various amounts of 4 per cent fat-corrected milk a year.

According to this table, the gross efficiency for 1,000-lb. cows yielding 5,000 lbs. of fat-corrected milk a year (about our United States average) is 20.8 per cent. At double this yield, 10,000 lbs., the gross efficiency rises to 30.9 per cent. According to this table, a 1,000-lb. cow producing 25,000 lbs. of 4 per cent fat-corrected milk a year would have a gross efficiency of 44.0 per cent.

1001. Feed good cows liberally, but not poor cows.—Unless cows of high productive capacity are fed with suffi-

cient liberality to provide them with the nutrients they need for the production of a large amount of milk and fat, their yield will soon decline to the level permitted by the nutrients they receive. Many cows which could be profitable producers are thus forced into the inefficient and unprofitable class, because their owners do not appreciate this important fact.

A well-fed dairy cow yielding about 1 lb. of butterfat a day requires nearly one-half of the feed she eats for maintaining her body. She therefore has left to use for milk production only about one-half of her feed. If she is fed only two-thirds as much, she will digest the scanty ration a trifle better, but she will still need nearly as much feed as before to maintain her body. As a result of the scanty feeding, she will probably have available for milk production only 30 per cent or less of the total feed she eats. This great reduction in the amount of feed that is left for milk production will much more than offset the slightly greater digestibility of a scanty ration. (101) Also, the overhead expenses per 100 lbs. of milk are greater when a cow is producing at a low rate.

It is just as unwise to overfeed a poor cow as it is to be stingy with a good producer. If a cow lacking productive ability is fed liberally, she cannot increase her milk production beyond her inherited capacity. All she can do is to store the excess nutrients in the form of body fat, instead of turning them into milk. The best plan is to get rid of such a cow, for she will not pay for her keep. If she is kept, it is important that she be fed according to her actual production, instead of being given as much grain as the good cows in the herd.

1002. Building a profitable herd.— The farmer who has a herd of low-producing, unprofitable cows cannot hope for any real success in dairying until he has secured a herd of good producers. He should therefore at once take steps to accomplish this result. Even if he starts with scrub or with beef-type cows, he can in 5 to 6 years make considerable improvement in his herd, if the calves are sired by a purebred, bred-for-production bull.

However, it is usually best to make more rapid progress by selling the poorest producers in the herd and replacing them with a few high-producing grade or pure-bred cows of the breed desired. If a good purebred dairy bull is then always used in the herd, and the lowest yielders are culled out each year, in a relatively short time he should have a herd of efficient producers.

The striking improvement which is made in one to three generations by using good purebred dairy bulls on scrub cows or on beef-type cows is shown in experiments by the Iowa, Minnesota, Oklahoma, and South Dakota Stations and the Canadian Department of Agriculture.[8]

In the Iowa experiment, for example, the original scrub cows, with good feed and care at the Station produced only 4,110 lbs. of milk and 192 lbs. of fat a year. Their daughters, sired by purebred bulls, produced 41 per cent more milk and their grand-daughters, carrying three-fourths of dairy blood, nearly twice as much as the original scrubs. The grades not only yielded more milk a day, but also were much more persistent milkers than the scrubs, whose lactation periods were short.

Even more important than the greater yield of milk, is the fact that the cost of feed for 100 lbs. milk was 13 per cent less for the three-quarter bloods, even though they were only heifers, than for their scrub grand-dams. Not only was the production rapidly improved by grading up, but also just as striking improvements were made in the conformation of the animals, especially in their udders. The grades, especially of the second cross, were stamped plainly with the breed characteristics of the purebred sires.

Scrub heifers, raised at the Station out of the scrub cows and the scrub bull, produced 10 per cent more milk and 13 per cent more fat a year than their scrub dams. This small increase, which was strikingly inferior to that from the use of purebred sires, was due to the fact

that the heifers were so fed and cared for as to develop fully what little capacity they did have for milk production.

In these trials the offspring from one of the purebred sires used on the scrub cows fell much below the others in productivity. This illustrates the well-known fact that to build up a herd a sire must be able to transmit high production, and not be merely a purebred.

By joining an artificial breeding association a dairyman in most of our dairy districts can now have his cows bred at moderate cost to an outstanding sire, even if he has only a few animals. He can thus gain the great advantage from the use of bulls which would be too valuable and high-priced for him to own alone.

1003. Type and production; purebreds vs. grades.—Good-producing dairy cows are usually of the dairy type, and poor producers show less of the dairy conformation and characteristics. However, even experts are often unable to tell by appearance alone whether a cow will be a profitable producer. Studies have shown that in purebred or high-grade dairy cows the correlation between type score and milk production is rather low.[9] The only reliable way of determining the productive capacity of a cow is from a record of the actual amount of milk and fat she yields.

In studies of the conformation of 1,000 purebred dairy cows and their production records, Swett of the United States Department of Agriculture found that length of head was the body measurement most consistently correlated with milk production.[10] Body depth, which indicates the size of the internal organs, was also definitely correlated with production.

Practically all dairymen now recognize that cows distinctly of beef type are not economical producers of milk. The dairy type and the beef type are the result of breeding for many generations with opposite objectives. The beef animal has been developed to store in its carcass the largest possible amount of meat. On the other hand, the dairy cow has been bred for the primary object of producing large yields of milk and butterfat. As a result, though a good dairy cow will put on flesh when she is dry, the impulse to milk production is so strong when she is in milk that even under liberal feeding she shows little or no tendency to fatten. Instead, she uses all the surplus feed above maintenance for the manufacture of milk.

Dairy-herd-improvement association records show that, on the average, purebred dairy cows produce more milk and fat and return a greater income over feed cost than do grade cows. This is because they have a greater inherited capacity for milk production. For example, in one study 63,739 registered purebred dairy cows in dairy-herd-improvement associations produced a yearly average of 8,443 lbs. of milk and 325 lbs. of fat, while 107,309 grade cows averaged 7,623 lbs. of milk and 298 lbs. of fat.[11] Still more important was the fact that the yearly net return over feed cost was $20 per head more for the purebreds.

It is possible by the use of excellent purebred sires in a grade herd for many years, combined with careful culling, to develop a herd that probably cannot be distinguished in appearance or production from a herd of purebreds. However, it must be borne in mind that the merits of high grades are due to their purebred ancestors, and not to the trace of scrub blood they still possess.

1004. Size of cow.—If equally well bred, the larger cows of a breed tend to produce more milk than the smaller ones. This is but natural, for a large cow has a greater capacity to consume and utilize feed. However, the amount of milk a cow will produce depends much more on her inherited dairy ability than upon her size. In developing a high-producing herd, one should therefore base his selection primarily on productive capacity rather than giving undue attention to size. If a large cow and a cow of moderate size produce equal amounts of milk, the cow of moderate size will be more profitable. This is because she will require somewhat less feed to maintain her body than the large cow.

In New York studies just completed,

the weights of the cows in 3,568 dairy-herd-improvement association herds of the various breeds were estimated by tape measurements, and the records of production and of feed consumed were grouped by weight classes in each breed.[12] Combining the results for all the breeds, an increase of each 100 lbs. in estimated live weight resulted in an average increase of 661 lbs. of 4 per cent fat-corrected milk. Not only was the milk production higher for the larger cows in each breed, but also the return over feed cost was decidedly greater. Similar results were secured in an earlier New York cost accounting study.[13]

There is an even greater difference in the net return per cow over all costs, including labor, for the larger cows in the breed. This is because the expenses other than feed costs are not much greater for large cows than for smaller ones.

One must, however, use good judgment and not develop a herd of cows that are too large in size for the particular conditions. For example, the stalls in the stable may be too small for very large cows, or the pasture fields may be so rough that they are better adapted to more agile cows of moderate size.

While the larger cows of a breed tend to excel on a per head basis, the smaller cows often surpass them in the efficiency with which they produce energy in milk from the total digestible nutrients in their feed.[14] This is because most dairymen tend to judge their cows by the amount of milk each cow produces, without paying enough attention to their relative sizes. Unless the smaller cow produces almost as much milk as the large one, she is often culled out because of low production.

The most accurate method of comparing the real merit of various cows is to compare them on the basis of their efficiency in converting total digestible nutrients in their feed into milk. Unfortunately, this is nowhere near as simple as to compare them on the basis of annual yield of milk and fat.

Certain investigators have believed that in cows equally well bred the milk yield tends to be directly proportional to the live weight.[15] On the other hand, others conclude that the milk yield is more nearly proportional to the 0.70 or 0.75 power of the live weight.[16]

1005. Weed out low-producing, unprofitable cows.—Although the average production of the dairy cows in the United States has been increased considerably as better feeding and breeding practices have been adopted by dairymen, the production is still only about 5,630 lbs. of milk and 225 lbs. of f[illegible]e cow. Even with average prices for [illegible] products, probably one-fourth or more of the dairy cows fail to pay for their feed and care. When dairy prices are low, the condition is even more serious.

The chief reason why such a condition is found now, when the principles of successful selection, feeding, and care of dairy cattle have long been known, is that the owners do not know which of their cows fail to yield enough milk to pay for their feed and care. They do not realize that though the gross income from their herd would be reduced [illegible] weeding out the "boarders," their profits would be decidedly increased.

It is therefore extremely important for a dairyman to secure the record of production of each cow in his herd. Fortunately, such records may be easily secured by the use of the milk scales and the Babcock fat test. Knowing the production of each cow and the approximate amount of feed she has consumed in a given period, the dairyman can discard the unprofitable animals, and gradually build up a herd of high producers at small expense by using a bred-for-production sire and saving the heifer calves from the best cows.

By this means the average yield of fat for the herd can be gradually increased year by year, until it is raised to 300 lbs., later to 350 lbs., and then even higher. As good cows sometimes have "off years" in production, animals should not be discarded after a single year's trial, if there is good reason to believe they will do better in the future.

1006. Keeping records of production.—For most farmers who have the

services available, belonging to a dairy-herd-improvement association (commonly abbreviated to DHIA) or to an owner-sampler club is the most convenient method of securing records of production on each of their cows. These services are relatively inexpensive, and the advice furnished concerning the feeding and management of the herd is of much value.

In dairy-herd-improvement associations in the United States a supervisor is employed who spends one day every month with each of the herds in the association. (In certain associations the tests are made bi-monthly, instead of each month.) Arriving on the farm in the afternoon, he weighs and samples the milk from each cow at milking time and also weighs the feed. The following morning this is repeated, after which the samples of milk from each cow are mixed thoroughly and tested for butterfat. From this day's record he computes the milk and fat production and the cost of feed for each cow for the current month. The data for each cow are recorded in the herd-record book, so that the dairyman has available the record of each cow for every month of the year. The tester also studies the local feed market and aids the dairyman in working out economical rations. In certain states, central testing laboratories have been set up, and the testing of the samples and the computation of the records is done there.

The production records of each cow for the first 305 days of each lactation are sent by the tester to the state agricultural college, from which they are transmitted to the Dairy Research Branch of the United States Department of Agriculture. These records are used in proving the transmitting ability of the sires used in the various herds and in making herd analyses, which are studies of the breeding worth of the various cow families.

The value of dairy-herd-improvement association records in increasing the efficiency of dairying is shown by the fact that in 1955 the average production of the cows in the associations in this country was 9,363 lbs. of milk and 372 lbs. of fat. For the same year the average yield of all cows milked in the United States was about 5,630 lbs. of milk.

In the owner-sampler type of cow testing, the dairyman weighs and samples carefully the milk from each cow for one day each month and then mails the samples and the record of weights to a central testing laboratory, usually conducted by the state college of agriculture. Here the samples are tested, the amount of fat is computed, and the records mailed back to the dairyman. This plan is especially convenient for farmers who have only a few cows or who live in localities where no dairy-herd-improvement association is available.

If a dairyman does not have available the services of a dairy-herd-improvement association or a dairy-record club, he can himself keep a record of each cow's production. The best way is to weigh and record each milking from every cow. This does not require much work, if a convenient spring balance is used and handy milk sheets for entry of the records. Such daily individual records make possible the feeding of each cow with the greatest economy, enable the herdsman to detect sickness quickly by the decline in milk flow, and aid in judging the efficiency of different milkers. Where the weight of each milking is recorded, it is sufficient to take samples for fat testing once a month for one or preferably two consecutive days. Those who feel that they cannot spend the time necessary to weigh each milking can obtain reasonably accurate records by weighing and sampling the milk regularly for one day each month.

1007. Official testing of dairy cows.—In this country two different types of official testing of dairy cows are provided by the dairy breed registry associations, the testing being done by supervisors, or testers, under the direction of the state agricultural college. In the *advanced registry* a breeder may enter one or more selected cows at any time for production records of either or both 305 or 365 days in length. Daily milk weights must be

kept by the dairyman. The test periods are preceded by a preliminary dry-milking, each cow being milked dry under the supervision of the tester.

In the *herd improvement registry* all the cows in the herd must be tested, with the possible exception of certain cows which have previous official records. A one-day test, without preliminary dry-milking, is conducted each month throughout the year, and the keeping of daily milk weights is not required.

The official production records are published by the breed associations. A high record increases the money value, not only of the individual cow, but also of her relatives, for progressive breeders in buying animals now rely more and more on production records instead of merely show-ring successes.

Recently, certain of our dairy breed associations have adopted plans and regulations under which the production records of the individual cows in a DHIA herd are accepted for publication and for the proving of sires, in the same manner as are the advanced registry records.

While a test covering one lactation period is a good index to the maximum productive capacity of a cow, a still better measure of her worth is a record over several consecutive years. Likewise, the best index to the value of the blood lines represented in a herd is provided by the records of all the cows in the herd, year after year. This is far more reliable than official tests on a few selected cows which are pushed to the very utmost when they are on test. For these reasons, the herd-test plan is becoming increasingly popular with breeders.

All dairymen recognize that successful reproduction within a normal period is fully as important as a record of high milk yield. To an ever increasing extent experienced breeders now favor, instead of a 365-day test, the 305-day test with the additional requirement that the cow calve within a definite period.

The feeding and care of cows for high records of production are discussed in Chapter XXVI.

II. Nutrient Requirements of Dairy Cows

1008. Requirements for milk production.—It has already been shown in Chapter X that the nutrient requirements of animals producing a large amount of milk differ greatly from the requirements of those being fattened or of those [illegible] muscular work.

For efficient milk production it is essential that dairy cows receive: (1) A liberal amount of total digestible nutrients or net energy; (2) a relatively large amount of protein, supplied by suitable dairy feeds; (3) at least a certain minimum amount of fat; (4) sufficient phosphorus, calcium, common salt, and other essential mineral nutrients; (5) an ample supply of vitamins A and D and of certain unknown factors or vitamins that may not be furnished by very re[illegible] rations; and (6) a ration that is palatable to the cows.

The amounts of nutrients required by any particular milk cow will depend, first of all, on her size, since maintenance requirements depend upon body size. Her needs will also depend on the amount of milk she is producing, and on its richness in fat. If she is a heifer, she will require additional nutrients for the growth of her body. When she is pregnant, there will be a still further need of nutrients for the development of the fetus. This latter requirement will be insignificant in amount during the first part of pregnancy, and will not be large even during the latter part. The nutrient requirements of dairy calves, dairy heifers, and dairy bulls are discussed in Chapter XXVII.

The Morrison feeding standards for dairy cattle are given in Appendix Table III. The standards for dairy cows give first the amounts of nutrients required for the maintenance of cows of various live weights, and second, the amounts of nutrients required for the production of 1 lb. of milk containing various percentages of fat. Also, the additional amounts of nutrients are given which are advised for cows during the last few weeks of pregnancy. For the reasons

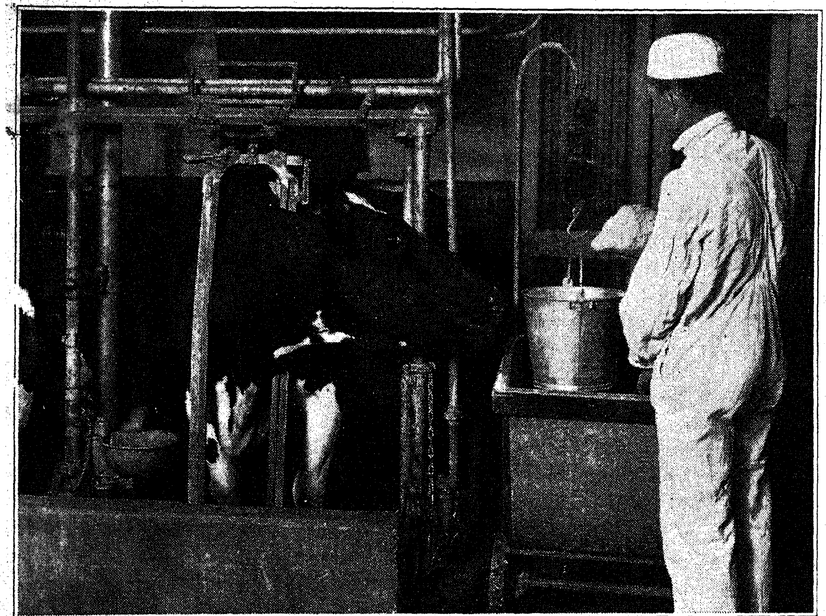
previously, a range is given in amounts of digestible protein and of digestible nutrients recommended the standards. (317, 325.)

Under usual conditions sufficient nu-nts should be supplied to meet the per figures in the range stated in the ndards. When protein-rich feeds are expensive, it may be most economi- feed no more protein than is required to meet the lower recommendations. Likewise, when grain and other concentrates are very expensive in comparison with hay and other roughages, it may be most profitable to supply only as much total digestible nutrients or net energy as recommended in the lower recommendations in the standards.

1009. Guides in selecting well-balanced rations.—Any intelligent dairyman can compute an economical, well-balanced ration for his cows by following the methods explained in Chapters XI and XII and familiarizing himself with the nutrient requirements for milk production which are discussed on the following pages. However, the computing of a balanced ration takes considerable time and trouble if one is not experienced in the process.

To simplify the selection of efficient rations for milk production, convenient feeding guides are given in Appendix Tables VII and VIII. By the use of these guides the balancing of rations is reduced to a simple recipe basis. Though these feeding guides are very simple, they have been worked out carefully on a scientific basis, so that they are reliable guides in practical feeding.

First, there are given in Appendix Table VII formulas for many different concentrate or grain mixtures which will make balanced rations when fed with the roughages indicated. One can readily determine which of the several mixtures in the proper group will be cheapest under the local conditions. If desired,



LIBERAL CONCENTRATE FEEDING NECESSARY FOR HIGH YIELD

Maximum milk production cannot be secured unless cows are fed a liberal amount of concentrates in addition to good roughage. Local conditions will determine what level of concentrate feeding will be most profitable. (From Wisconsin Station.)

changes can be made in these formulas by following the directions given in the paragraphs which immediately precede the formulas.

1010. Determining how much concentrates each cow needs.—After selecting an economical concentrate mixture that will make a balanced ration with the roughage to be fed, it is next necessary to know how much of the concentrate mixture each cow in the herd should receive. Various "thumb rules" are often used for estimating this. A more convenient and also more accurate method is to use the "Grain Feeding Tables" given in Appendix Table VIII.

The first of these tables is for use when the cows are not on pasture. It states the number of pounds of a good concentrate mixture, or so-called "grain mixture," required by cows producing various amounts of milk of different fat percentages, when various amounts of roughage are eaten. The second table similarly shows the amounts of concentrates needed by cows on different grades of pasture. Before using these tables, one should read carefully the directions that immediately precede them.

Sufficient amounts of grain mixture are advised in these tables to meet the recommendations of the feeding standards and to maintain good yields of milk under usual conditions. When concentrates are very expensive in comparison with roughages, it may then be most economical to feed a smaller amount of grain mixture than stated in the tables.

It is recommended in the paragraphs that precede the tables that excellent cows which have run down in flesh should be fed somewhat more grain mixture during the latter part of the lactation period than is stated in the tables. Also, heifers need a trifle more grain mixture than shown in the tables, because they are still growing.

It is well worth while for a dairyman to understand thoroughly the method of computing economical rations which are balanced in accordance with the feeding standards. He will then know how to make balanced rations under any special conditions that may arise. However, from the standpoint of his returns, the most important point is to be sure to feed balanced rations, though he has not taken time to work them out himself. In any case, if in doubt as to the best ration to use, a dairyman will find his county agent or his agricultural college and experiment station ready to advise him.

In computing rations for dairy cows, it is necessary to know their approximate weights. If one does not have suitable scales available for weighing the individual cows, their weights can be estimated from a measurement of the heart girth. Appendix Table IX shows the approximate weights of dairy cows having different heart girths.

1011. "Thumb rules" not accurate guides.—Various "thumb rules" have been widely used for estimating the amount of grain mixture required by cows producing different amounts of milk and fat. However, none of these thumb rules is so convenient or so accurate as the grain feeding tables.

For example, a common thumb rule is: Feed 1 lb. of grain mixture per day for each $2\frac{1}{2}$ to 4 lbs. of milk, depending on the richness of the milk and the quality of the roughage fed. Under most conditions this and similar thumb rules underfeed the high producers and overfeed the poor cows. This is because these rules do not take into consideration the important fact that when a cow is fed a liberal amount of good roughage, she receives a greater amount of nutrients than she needs for mere body maintenance. Her concentrate allowance should accordingly be based, not on the total amount of milk she yields, but on the amount she is producing beyond the amount which she can make from the roughage.

Certain "thumb rules" have been devised which take these facts into consideration. For example, one such rule, for use when good roughage is fed in the usual amounts, is: For Holsteins, feed 0.4 lb. of concentrates for each pound of milk above a yield of 16 lbs.[17] Similar rules are stated for cows of other breeds.

While these rules are more accurate than the older "thumb rules," they are less convenient than the grain feeding tables in Appendix Table VIII. Also, they are based merely on the usual amounts of good roughage, and cannot be used when a very liberal amount of excellent roughage is fed, or when, on the other hand, only a scanty allowance of roughage is used. The grain feeding tables give definite recommendations to fit these varied conditions.

1012. Feeding standards vs. actual requirements.—In the following discussions concerning the nutrient requirements of dairy cows and concerning the recommendations made in various feeding standards, the purpose and nature of feeding standards must be borne clearly in mind. Feeding standards are intended as practical, convenient guides for the proper feeding of the various classes of stock. They are not statements of the theoretical minimum requirements of nutrients.

It has been shown previously that when animals are fed a liberal ration, they digest a slightly smaller percentage of the food nutrients than when they receive a scanty ration. (**101**) Practically all the experiments to determine the digestibility of various feeds have been conducted, not with liberally-fed dairy cows, but with steers or wethers fed rather limited rations. This plan has been followed because it is essential in digestion trials that the animals eat all the feed that is offered them, without leaving any waste whatsoever.

Tables giving the digestible nutrients in various feeds, such as Appendix Table I of this volume, must consequently be computed from these digestion coefficients, since they are the only ones available. It must therefore be borne in mind that well-fed dairy cows will really secure from the feeds they eat slightly smaller amounts of nutrients than are shown in Appendix Table I. This fact is, however, fully taken into consideration in the recommendations made in the Morrison feeding standards for dairy cows. This has been done by placing the advised amounts of nutrients slightly above the theoretical requirements, to cover the decrease in digestibility when liberal rations are fed.

In certain feeding standards for dairy cows no such correction factor has apparently been applied. As a result, dairy cows will be under-fed, if rations are computed according to these standards and with the available figures for the digestible nutrients in various feeds.

1013. Requirements for maintenance.—The Morrison feeding standards recommend from 0.60 to 0.65 lb. digestible protein and 7.0 to 7.9 lbs. total digestible nutrients for the maintenance of a 1,000-lb. cow. Stated in terms of net energy for those who may wish to compute rations on this basis, the requirement for such a cow is 5.6 to 6.3 therms of net energy. The amounts of nutrients recommended for other live weights have been computed on the basis that maintenance requirements are proportional not to the live weight, but to the 0.87 power of the live weight.

This factor was selected because it was believed that the maintenance needs were not strictly proportional to live weight, for the reasons discussed in an earlier chapter. (**238**) By using the 0.87 power of the live weight instead of some other factor, rations computed according to the standards seem to agree best with good dairy practice.

In making the recommendations in these standards for the maintenance of dairy cows, the author has carefully considered the extensive investigations of Hills and associates at the Vermont Station over a period of 14 years,[18] and also the earlier studies of Haecker,[19] and the investigations of Eckles,[20] of Armsby,[21] of Forbes and associates,[22] of Brody and Proctor,[23] and of Möllgaard and Hansson.[24]

A special committee of the National Research Council has presented "Recommended Nutrient Allowances for Dairy Cows."[25] In these standards no range is given in the amount of digestible protein and of total digestible nutrients advised. The amounts of digestible protein recommended for maintenance are approximately the same as the lower set of fig-

ures in the Morrison standards, and the amounts of total digestible nutrients similar to the higher set of figures in the Morrison standards.

From studies in New Zealand, McMeekan has estimated that cows on pasture need about 50 per cent more total digestible nutrients than barn-fed cows.[26] This is because of the work done in travelling about the pasture and in gathering their food.

1014. Requirements for milk production.—Extensive investigations have been conducted to determine the amounts of nutrients cows need, in addition to their maintenance requirements, for the production of milk. These investigations have been carefully considered in drawing up the recommendations in the Morrison feeding standards. For those especially interested in the nutrient requirements of dairy cows, somewhat detailed information concerning the studies on this subject is given in articles which follow.

The investigations have proved that fairly good production can be secured when cows receive in their feed, in addition to the allowance for maintenance, only about 1.25 times as much digestible protein as the amount of protein in the milk they produce. However, cows of good productive capacity may yield somewhat more milk and fat when the protein allowance is greater than this. Supplying, in addition to the maintenance needs, more than 1.50 to 1.60 times as much digestible protein as there is protein in the milk, does not increase the milk yield appreciably.

In the Morrison standards the lower figures in the range of allowances for digestible protein provide only about 1.25 times as much digestible protein as the amount of protein in the milk. The higher figures in the range of allowances supply about 1.5 times as much digestible protein as there is protein in the milk.

The author believes it is the best plan under usual conditions to feed cows capable of producing 1 lb. or more of butterfat a day, according to the more liberal recommendations. If protein-rich feeds are unusually expensive, it may be most economical, even in the case of good cows, to supply no more than the lower amounts of protein shown in the standards.

1015. Investigations on protein requirements.—Haecker of the Minnesota Station was apparently the first scientist to appreciate that the nutrient requirements of dairy cows depended not only on the amount of milk produced, but also upon its richness. Milk that is rich in fat is also considerably higher in protein than that which has less fat. Haecker therefore recommended in his feeding standards not only a greater amount of total digestible nutrients but also a greater amount of digestible protein for each pound of milk rich in fat than for milk lower in fat.

The Haecker standards recommended 0.7 lb. digestible protein daily per 1,000 lbs. live weight for maintenance and, in addition, amounts for each pound of milk which provided about 1.5 times as much digestible protein as the amount of protein in the milk.[27] These protein recommendations were much lower than the old Wolff-Lehmann feeding standards, which advised nearly twice as much digestible protein as the milk of average composition.

The recommendations in the Armsby standards, the Eckles standards, the Möllgaard standards, and the Hansson standards, which are based on digestible true protein, must be converted into digestible crude protein (called digestible protein in this volume) to compare them with the standards previously discussed. When this is done and the amounts of protein recommended for maintenance are added to the amounts for milk production, it will be found that about the same amounts of protein were advised in the Armsby standards as in the Haecker standards.[28] Somewhat greater amounts were recommended in the Hansson standards, the Möllgaard standards, the Eckles standards, and also in the standards presented by Ellett, Holdaway, and Harris of the Virginia Station.[29]

In extensive investigations by Hills and associates at the Vermont Station, mostly with grade Jerseys, the cows produced satisfactorily on rations providing 1.26 to 1.46 times as much digestible protein, in addition to maintenance, as the milk contained.[30] The yield on such rations was nearly as high as on a more liberal protein supply. However, the cows were not high producers, as they yielded only 0.78 to 0.92 lb. fat daily, on

the average. With such cows the production was not seriously reduced when rations still lower in protein were fed.

It was found in Wisconsin and Pennsylvania metabolism experiments that cows of fairly good production will remain in nitrogen balance (without losing protein from their bodies) if the ration provides, in addition to maintenance needs, 1.25 times as much digestible protein as the milk contains.[31]

In New York experiments cows fed early-cut mixed clover-and-timothy hay and corn silage for roughage produced a daily average of 33.1 lbs. milk (equated to a basis of 3.5 per cent fat) when fed a concentrate mixture containing 16 per cent total protein.[32] The average yield of other cows fed a concentrate mixture having 20 per cent protein was 34.4 lbs. The ration lower in protein furnished, in addition to maintenance needs, 1.2 to 1.4 times as much digestible protein as was contained in the milk, and the latter ration about 1.7 times as much. Though the average yield of milk was slightly greater on the 20-per-cent-protein mixture, the difference was too small to be statistically significant.

In these experiments a concentrate mixture having 24 per cent total protein did not produce any more milk or fat than did the 20-per-cent mixture, when fed with the first-class mixed hay and corn silage. On the other hand, the milk yield was decidedly decreased and the digestibility of the ration was much lower when a concentrate mixture was fed that had only 12 per cent protein. After deducting 0.6 lb. digestible protein daily per 1,000 lbs. live weight for maintenance, this ration did not supply quite as much digestible protein as was contained in the milk.[33] The cows fed this ration therefore had to draw on their bodies for some of the protein they put into their milk.

In similar Ohio experiments, in which cows were fed good mixed legume-and-grass hay and corn silage for roughage, the yield of milk was 6 per cent greater on a concentrate mixture having 19.0 per cent total protein than on one with only 13.8 per cent.[34] The first ration supplied, in addition to the maintenance needs, about 1.5 times as much digestible protein as the milk contained, and the lower-protein ration about 1.25 times as much.

In experiments by the United States Department of Agriculture cows fed a concentrate mixture having only 10 to 12 per cent protein, with timothy hay, corn silage, and a little alfalfa hay for roughage, produced as much milk as when fed a concentrate mixture having more protein.[35] The low-protein ration supplied only 1.25 times as much digestible protein as in the milk in addition to a maintenance allowance of only 0.5 lb. digestible protein daily per 1,000 lbs. live weight. Differing from this result, in a previous experiment the milk production was much less on such a low-protein ration than on a ration having more protein.[36]

In certain other studies rations furnishing even more protein than recommended in the higher set of figures in the Morrison standards have tended to produce a little more milk than rations having less protein.[37]

In Ohio experiments cows of high productive capacity yielded a surprising amount of milk when fed even less than 1.25 times as much digestible protein, in addition to maintenance, as their milk contained. On a low-protein ration having a nutritive ratio of 1 : 11, Holstein cows produced as much as 11,013 lbs. of 4 per cent milk in a year.[38] However, the yield was much less than from the same cows when fed rations containing an adequate supply of protein. On the protein-poor ration the digestibility of the feed was also considerably decreased. It was therefore necessary to feed very liberal amounts of concentrates to secure fair production. The cows lost about 200 lbs. in weight during milk production, but regained their original weights during the dry period.

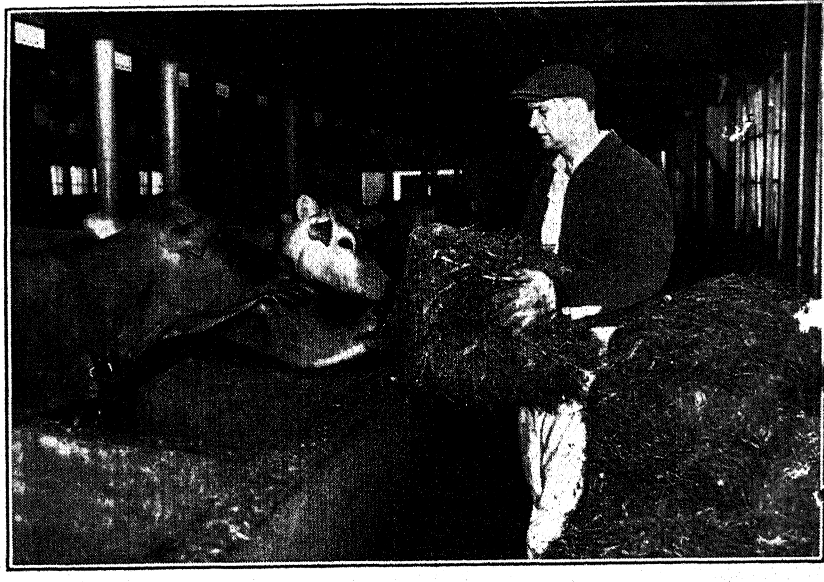
In the Ohio experiments other cows were fed rations extremely rich in protein, having a nutritive ratio of 1 : 2. There were no marked injurious effects from this great excess of protein, although there was a tendency toward delayed breeding on this ration and a longer period than normal between calvings.

The amounts of digestible protein recommended by the special committee of the National Research Council, for the production of milk of the various fat percentages are between the lower and

upper sets of figures in the Morrison standards.[25]

1016. Importance of protein content of the roughage.—The percentage of protein that is needed in the concentrate or grain mixture to make a properly-balanced ration will depend on the protein content of the roughage that is fed. When the only roughage is alfalfa hay, soybean hay, or cowpea hay (all of which are very rich in protein), the is not actually needed. Also, as is shown later, it is wise to add a phosphorus supplement to such a ration. (1035)

The amount of protein supplied by the roughage will be somewhat less when red clover hay is fed instead of alfalfa hay. However, a ration of 24 lbs. of good clover hay and 12 lbs. of corn grain provides enough protein for a cow producing about 40 lbs. of 3.5 per cent milk daily.



PROTEIN CONTENT OF ROUGHAGE IMPORTANT

The percentage of protein that is needed in the concentrate or grain mixture depends on the protein content of the roughage that is fed. (From New York State College of Agriculture, Cornell University.)

amount of protein supplied by the hay will be so large that there will be plenty for a cow of good productive capacity, when merely corn grain or a mixture of corn and other grain is fed with the hay.[39]

For example, a ration of 24 lbs. of average alfalfa hay and 18 lbs. of corn grain will furnish sufficient protein for a 1,200-lb. cow producing 60 lbs. of 3.5 per cent milk. For high-producing cows it may be wise to include wheat bran or some other protein-rich concentrate to make the mixture more palatable, even though the additional amount of protein

Since young, actively growing pasture plants are fully as rich as legume hay in protein, on the dry basis, it is unnecessary to use a concentrate mixture high in protein for cows on excellent pasture. This matter is discussed further in Chapter XXVI.

When non-legume roughage, such as corn or sorghum silage, is fed along with legume hay, or when the hay is mixed legume-and-grass hay, considerably less protein will obviously be supplied by the roughage. The concentrate mixture must then be richer in protein than when pure legume hay is the only roughage. How-

ever, less protein is needed in the concentrate mixture under such conditions than many dairymen believe necessary.

Many different concentrate mixtures are given in Appendix Table VII which are well adapted for use with various types of roughage. These example formulas will be helpful in deciding what kind of a mixture to feed under one's local conditions.

If good alfalfa hay and corn silage are full-fed for roughage, such a grain mixture as one-half ground corn and one-half ground oats is satisfactory for cows yielding about 1.0 lb. of butterfat a day. For higher-producing cows and when the amount of alfalfa hay is limited, protein supplements should be added to the ration.

Several experiments have shown clearly that no protein supplement is needed when cows of any usual rate of production are fed plenty of alfalfa hay and corn silage with a grain mixture of corn and oats.[40] In these trials the milk yield was fully as high on the home-grown ration as when protein supplements, such as linseed meal, soybean oil meal, or cottonseed meal, were added.

Dairy cows yielding 1.25 lbs. of fat a day remained in nitrogen balance, losing no protein from their bodies, in metabolism experiments at the Wisconsin Station when fed a ration of alfalfa hay, corn silage, and grain.[41] On the other hand, they lost protein when clover hay, lower in protein than alfalfa, was substituted for the alfalfa hay.

That very high milk production can be secured without any protein supplement, when abundant protein-rich roughage is fed, is well proved by the results achieved by an Illinois dairyman.[42] His herd averaged 525 lbs. of fat a year on home-raised feed, without any protein supplement whatsoever. The cows were fed a grain mixture of half corn and half oats at a moderate rate. In winter they had for roughage all they would eat of legume hay and legume-grass silage. In summer they were on first-class pasture and had a little hay in addition.

1017. Wasting protein supplements with legume hay.—Often, when dairymen who have been growing but little legume hay change their cropping practices and provide their cows with an abundance of good legume hay, they fail to reduce the amounts of protein supplements in the concentrate mixtures they feed. For example, in the northeastern states some dairymen continue to feed concentrate mixtures containing as much as 20 to 24 per cent total protein, after they have provided their cows with plenty of alfalfa hay. Since protein supplements, such as soybean oil meal and linseed meal, are usually higher in price than the cereal grains or other low-protein concentrates, this is then decidedly uneconomical. The cows would produce just as much milk and fat if only sufficient amounts of protein supplements were fed to balance the ration.

Even with good mixed hay for roughage, smaller amounts of protein supplements are needed than have been fed by many dairymen, especially in the eastern states. The experiments which have previously been reviewed show that with such roughage a concentrate mixture containing 16 to 18 per cent of total protein furnishes sufficient protein for satisfactory production. When protein supplements are high in price, a mixture containing only 16 per cent protein will generally be more economical with such roughage than one higher in protein. It must be borne in mind, however, that with mixed hay containing only a small proportion of clover or that which is late-cut, somewhat more protein than this should be supplied in the concentrate mixture.

It is interesting to note that when a concentrate mixture unnecessarily high in protein is fed with legume hay, often the cows do not clean up the leaves well. Their instinct seems to let them know that they do not need the protein-rich leaves. If a concentrate mixture lower in protein is later fed, the cows are then apt to eat all the leaves.

1018. Quality of protein.—It has been shown in Chapter V that the kind or quality of protein in rations for milk cows is of little importance when the rations contain good roughage and are

made up of feeds that are otherwise satisfactory. (127) This is because the bacteria in the paunch of ruminants make complete proteins, containing all the essential amino acids, from proteins of poor quality and even from simpler nitrogenous substances. Further on in the digestive tract, ruminants digest the bacteria and thus use the bacterial protein which has been formed.

In 5 experiments at the New York (Cornell) Station with high-producing cows fed corn silage and mixed hay low in legumes for roughage, a concentrate mixture having poor-quality protein gave as good results as a mixture having better-quality protein and also more variety.[43] The first mixture consisted of corn gluten feed, corn gluten meal, ground corn, and ground oats, with molasses in 2 of the tests. The mixture with better-quality protein had soybean oil meal, linseed meal, cottonseed meal, distillers corn dried grains, corn gluten feed, ground corn, and ground oats, with or without molasses. For swine or poultry this mixture would unquestionably have given better results than the first one.

Similarly, in a Wisconsin experiment dairy heifers grew just as well when gluten meal was used to balance a ration of corn silage, timothy hay, corn, and oats, as when the supplements were linseed meal and wheat bran.[44] Also, the growth was about as rapid on the rations with no legume hay as when alfalfa hay was fed.

When the roughage is of poor quality, then the kind of protein in the concentrate mixture may be of importance. For example, in a Wisconsin metabolism experiment corn gluten feed was inferior to protein supplements having protein of better quality, when fed with cereal grain and with corn stover as the only roughage.[45] On the other hand, when the roughages were clover or alfalfa hay and corn silage, corn gluten feed was nearly as efficient a protein supplement as linseed meal, cottonseed meal, or distillers dried corn grains.

Similarly, in metabolism experiments in Scotland the protein of a ration containing grass silage or fresh or dried young grass was more efficient for milk production than the protein of a ration with no good roughage.[46] As shown later, urea gives much better results when substituted for part of the protein in a ration with good roughage than when the roughage is poor. (1019) A possible reason for the different results with good roughage and with poor roughage has been mentioned in Chapter V. (127)

1019. Urea as a protein substitute.—The use of urea as a substitute for part of the protein in rations for ruminants and the conditions affecting its utilization have been discussed in Chapter V. (129) Many experiments have been conducted to determine the value of urea in dairy rations.[47] In some of the trials the results have been entirely satisfactory with urea as a partial protein substitute, while in other trials rations balanced with ordinary protein supplements have been somewhat superior.

For example, in Virginia trials urea was an effective substitute for cottonseed meal in rations for dairy cows. In contrast, in English experiments on 12 farms the addition of peanut oil meal to a low-protein ration significantly increased milk production, while the addition of urea had little effect.

In trials in Hawaii, Massachusetts, and New York the milk yield was appreciably less when urea replaced soybean oil meal or other protein supplements in the concentrate mixture. When continued on a concentrate mixture containing urea for a considerable time, the cows have tired of the mixture in some trials.

Urea is utilized best when it is fed in combination with grain or some other starchy concentrate. Molasses is not a satisfactory substitute for all the grain. Also, urea gives better results when used in a ration with good roughage than when all the roughage is poor. In New York trials dairy heifers did poorly on a ration of molasses, urea, and late-cut grass hay, while the gains were satisfactory when soybean oil meal was fed as a protein supplement. The results were somewhat better when a little ground corn

was added to the molasses, urea, corn, and hay ration, and were satisfactory when the poor hay was replaced by good mixed hay furnishing considerable protein.

We may conclude that urea is a useful substitute for part of the protein supplements in a concentrate mixture for dairy cows, when there is a shortage of protein supplements or when they are very high in price. However, urea-containing concentrate mixtures are never superior to mixtures in which the same amount of nitrogen is supplied by ordinary protein supplements, and the urea mixtures may not be quite so efficient.

1020. Fat in dairy rations.—It has been shown in Chapter X that the fat in milk can be made from other food nutrients than fat, but that an animal can apparently make milk fat more readily from food fat than by synthesizing it from carbohydrates. Therefore, unless the ration for a high-producing cow contains at least a certain minimum amount of fat, the yield of milk and of butterfat will be decreased. (**303**)

Dairy rations now often have less fat than formerly, because of the increased use of the solvent process in the production of soybean oil meal and other oil meals. It is therefore important to know how this lower fat content of the ration affects the milk yield.

The most extensive investigations on this problem are 17 experiments at the New York (Cornell) Station.[48] In these trials low-fat concentrate mixtures having an average of only 2.7 per cent fat were compared with higher-fat mixtures averaging 6.5 per cent in fat. These mixtures were fed with such roughages as timothy or mixed hay plus corn silage or dried beet pulp. On the average, the yield of 4-per-cent milk was 1.4 lbs., or 4 per cent, greater on the high-fat concentrate mixtures. It was concluded that 100 lbs. of a concentrate mixture having 4 per cent fat would produce as much milk as 104 lbs. of a similar mixture with only 2 per cent fat.

When a concentrate mixture containing 4 per cent fat was fed with corn silage and mixed clover and grass hay for roughage, the ration supplied about 70 per cent as much fat as there was in the milk. Somewhat more than 30 per cent of the milk fat was therefore made from other nutrients in the ration, for part of the so-called "fat" in feeds consists of other substances than true fats. (**12**)

These experiments, together with other studies and the experience of dairymen in recent years, show that good milk production, if not quite maximum yields, can be secured on concentrate mixtures containing only 2.5 per cent fat.[49] However, a concentrate mixture having more fat is worth slightly more per ton. In the New York experiments it was found that the difference in yield due to a low fat content of the concentrate mixture was less when abundant good roughage was fed. Also, adding soybean oil or corn oil to a low-fat ration was not nearly so beneficial as supplying the same amount of fat in natural feeds.

When by-product animal fat is available at a price that makes its use for stock feeding economical, such fat can be added by manufacturers of formula feeds to increase the fat content and energy value. (**134**) For example, in a recent Arizona trial the milk and fat production was slightly increased when 7 per cent of stabilized animal fat was added to a low-fat dairy concentrate mixture of rolled barley, dried citrus pulp, molasses, and cottonseed meal.[50]

1021. Total digestible nutrients or net energy for milk production.—In the Morrison feeding standards a range is given in the amounts of total digestible nutrients and of net energy recommended, in addition to the maintenance needs, for each pound of milk of the various fat percentages. The recommendations for milk containing various percentages of fat have been computed on the basis of the Gaines' formula for estimating the energy content of milk. (**999**)

In the opinion of the author, the estimated net energy values given in Appendix Table II are a more accurate basis for computing rations for milk production than the total digestible nutrient

values in Appendix Table I. This opinion has been corroborated by recent investigations in which cows have been fed various proportions of hay and concentrates.[51]

Where experiments have definitely shown that a particular feed, such as oats or wheat bran, has a higher value for milk production than it does for meat production, separate net-energy values are given for milk production.

The higher amounts of total digestible nutrients and of net energy stated in the standards are advised under most conditions. To meet these recommendations it is necessary, in the case of cows producing good yields of milk, to feed considerable amounts of concentrates, in addition to a liberal supply of roughage. The grain feeding tables (Appendix Table VIII) show the amounts of concentrate mixture, or grain mixture, needed to meet these recommendations for cows producing different amounts of milk when the roughage supply is very liberal, average, and scanty.

If one wishes to secure maximum yields from a cow capable of high production, even more concentrates must be supplied than called for by these recommendations. Also, when milk is very high in price in comparison with the cost of concentrates, more liberal concentrate feeding may be profitable.

On the other hand, when roughages are very cheap in comparison with concentrates, then it will be most profitable to supply no more total digestible nutrients than called for in the lower figures of the standards. When good cows are thus fed, their milk yield will decline more rapidly during lactation than when their nutrient supply is more liberal, and their total yield for the year will be considerably less. Nevertheless, such feeding may produce a greater net return when concentrates are very expensive. It is pointed out later in this chapter that in districts where alfalfa hay is very cheap, compared with grain or other concentrates, it may be most profitable to feed an abundance of hay and no concentrates whatsoever, even to good cows. (**1027**)

Cows need additional nutrients during the latter part of lactation and in the dry period, to provide for the development of the unborn calf and to get the cow into good condition before calving. (**1082**) For the last 2 or 3 months before calving, the amounts of nutrients shown in the feeding standards under "C. Additional allowance for last 2 to 3 mo[illegible] of pregnancy" should be added to [illegible] lowance for maintenance and the [illegible] ance for milk produced.

Since milking heifers are stil[illegible] ing, they need the additional am[illegible] feed stated under "Extra feed for [illegible] heifers," in the articles immedia[illegible] ceding Appendix Table III.

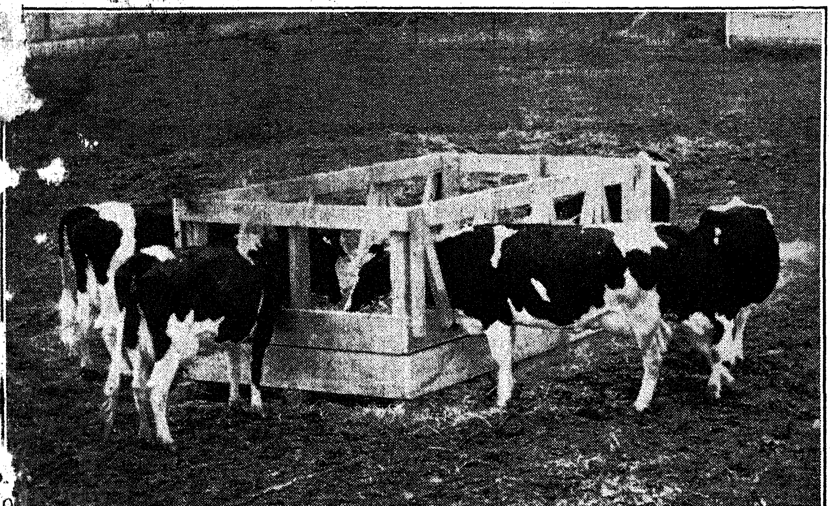
In making the total digestible [illegible] trient and net energy recom[illegible] in the Morrison standards, the variou[illegible] vestigations on this subject have been carefully considered, especially the studies of Brody of the Missouri Station and Gaines of the Illinois Station.[52] In the report of the special committee of the [illegible] tional Research Council, which has [illegible] mentioned previously, approximatel[illegible] same allowances of total digestible [illegible] trients are advised per pound of m[illegible] as the higher set of figures in the Mo[illegible]ison standards.[25] In that report no net energy recommendations are made.

1022. Abundance of high-quality roughage saves concentrates.—In order to secure the greatest net returns in dairying, one of the first essentials under usual conditions is to provide the [illegible]s with an abundance of first-class roughage. If cows are furnished all the high-quality roughage they will eat, they consume considerably more than they [illegible]ld of poorer roughage. High-quality roughage, such as well-cured legume hay or corn silage, is also richer in digestible nutrients than poorer roughage, such as ordinary grass hay. Therefore, when cows have an abundance of good roughage, they will get from the roughage a much larger proportion of the nutrients they need for high production, than when the roughage is poor or scanty in amount.

For example, Grain Feeding Table A (Appendix Table VIII) shows that when a cow yielding 40 lbs. of 3.5 per

cent milk daily is fed good roughage very liberally she needs only 9.6 lbs. of concentrate mixture a day. However, if she is fed poor roughage or a scanty amount of good roughage she may need about 15.2 lbs. of concentrates. Similarly, if this cow is on excellent pasture she will need only about 6.0 lbs. of concentrates to maintain high production, while over ... as much will be needed on fair ... tain ... su ... amo ...

During 4 years, the average yield of milk on twice-a-day milking was 12,347 lbs. and the average yield of fat 410 lbs. The fat average was 400 lbs. or over each year. To secure this high yield, the cows received an average of 4,035 lbs. hay and 8,093 lbs. corn silage, were on pasture an average of 160 days, and were fed an average of only 2,577 lbs. grain mixture. The rate of grain feeding was much lower than usual in this intensive



AN ABUNDANCE OF ROUGHAGE SAVES CONCENTRATES

When the supply of forage on pasture is scanty, cows should be fed hay or silage in addition, so they can get their fill of roughage. A rectangular rack reduces waste and may be used for feeding either hay or silage. (From New York State College of Agriculture, Cornell University.)

The excellent production that can be secured when well-bred cows have an abundance of high-quality roughage and a moderate amount of concentrates is well shown by the records made by a dairyman in a New York dairy-herd improvement association.[53] The cows in this herd, which were chiefly Holsteins, had all they would eat of good legume or mixed hay and corn silage during the barn-feeding season. In summer excellent pasture was provided on well-fertilized fields. Whenever the pasture became at all scanty, silage or silage and hay were fed in addition. Thus the cows were filled up with high-class roughage throughout the year.

dairy district, being 1 lb. of grain mixture for each 4.8 lbs. of milk. For the 4-year period the average annual cost of feed per cow was $89.50; the average value of product, $285.25; and the average net income over feed cost $195.75.

A New Hampshire dairyman who made full use of pasture and hay mixtures containing Ladino clover secured as large a milk yield as this, with even less concentrates.[54] Though he fed an average of only 1,220 lbs. of grain mixture per cow per year, he obtained an average of 13,030 lbs. milk and over 400 lbs. of fat. This was made possible by feeding in winter an abundance of early-cut, high-quality hay, along with silage,

and providing excellent pasture on well-fertilized fields throughout the growing season. Before he used the efficient, new-type pasture and hay mixtures, he fed over twice as much grain mixture a year, but the average milk yield was less.

1023. Good roughage cannot entirely replace concentrates.—The needs of good cows for total digestible nutrients and net energy cannot be fully met by supplying only an abundance of roughage, without the feeding of any grain or other concentrates. This is true even when they have the best of pasture during the growing season and are fed an abundance of good hay and silage the rest of the year.

If cows capable of high production are fed only roughage of any ordinary quality, they will produce decidedly less milk than when fed the usual amount of concentrates in addition. This is first of all because such roughage is so bulky and so low in total digestible nutrients and net energy that a cow cannot eat enough such feed to supply the amount of nutrients required for high production.

When the ration does not furnish enough net energy to meet the needs for maintenance and for the amount of milk a cow is yielding, she can draw on her body stores for a brief time, provided that she is in good condition of flesh. However, her milk yield will soon fall to the level that is permitted by her nutrient intake.

If the roughage is of superlative quality and is fed in abundance, so the cows can select only the leaves or other finer and more nutritious parts and leave the stems, such roughage alone may produce nearly as much milk as when concentrates are fed in addition. In a 5-year New Jersey experiment cows were fed in winter unusually good alfalfa hay (U.S. No. 1 extra green and leafy, second and third cutting) and well-eared corn silage.[55] The hay was fed 4 times a day in greater amounts than the cows would eat, so they could leave the stems. In summer the cows were grazed on excellent legume-grass pasture in a high state of fertility and were fed the excellent hay in addition.

On this unusually excellent supply of roughage, without any concentrates, cows produced 81.5 per cent as much fat-corrected milk a year as others that were fed concentrates in addition at the rate of 1 lb. of concentrate mixture per 3 lbs. of milk. Other cows fed concentrates at the low rate of 1 lb. for each [illegible] lbs. of milk produced 94.5 per cent as much milk as those fed concentrates more liberally.

1024. Is there a lactation factor?—Opinions of scientists differ as to whether the deficiency of net energy in a ration of roughage alone for dairy cows is the only cause of the lower production on such rations. From their Michigan experiments Huffman and associates have concluded that most concentrates and certain other feeds supply an unknown "lactation factor or factors" needed for high milk production.[56] In the experiments, after cows had declined in milk production on alfalfa hay alone, part of the hay was replaced by an amount of grain or other feeds which furnished the same amount of total digestible nutrients. In most cases the milk yield increased appreciably. Similar results were secured in Oregon and West Virginia trials, and in an Arizona experiment dried grapefruit pulp increased milk production of cows previously fed alfalfa alone more than did an equal amount of the usual type of concentrate mixture.[57]

When grain or other concentrates replaced part of the hay on an equal total-digestible-nutrient basis in these trials, the ration of course had more net energy, and this could well have been the cause of the increase in milk production. However, in the later Michigan experiments the substitution was made on an equal net energy basis, but the milk yield again seemed to be increased in most cases.

In the Michigan trials early-cut hay of high quality seemed to be higher in the lactation factor than ordinary hay. Well-eared corn silage apparently supplied more of the factor than corn silage with little grain. However, excellent

early-cut hay has more net energy per pound of total digestible nutrients than does ordinary hay, and well-eared corn silage much more than silage with few ears.

The results of Maryland and New York experiments differ from those of the Michigan investigations.[58] In trials with cows whose milk yield had declined on hay alone, the production was not increased when part of the hay was replaced by an amount of concentrates that furnished equal net energy. The investigators therefore concluded that the increase in yield that occurs under usual conditions when concentrates are added to hay alone could be explained chiefly or entirely on the net energy basis.

From the practical standpoint, no matter whether or not there is an unknown lactation factor which is required for high milk production, all agree that maximum milk yield cannot be secured on only roughage of any usual quality. Also, there is agreement that excellent, early-cut hay will produce more milk than ordinary hay, and that well-eared, well-matured corn silage is superior to silage with few ears.

1025. Determining the most profitable level of concentrate feeding.—Determining the most profitable amount of concentrates to feed dairy cows in addition to an abundance of good roughage is one of the most important problems of dairying. The answer will depend on the relative cost of nutrients in roughages and concentrates, on the price received for the milk, and on the productive capacity of the cows. Many experiments have been conducted to study this problem, of which the most extensive were the "input-output" experiments conducted by the United States Department of Agriculture in cooperation with 10 state experiment stations.[59]

These and other investigations have shown that when cows capable of good production are changed from the usual method of feeding to roughage alone, fed in abundance, they will usually yield only about 75 per cent as much milk and fat as on a normal ration. If continued on roughage alone for consecutive years, their yield will drop still further. This is because they tend to run down in condition, or because they become depleted of the "lactation factor" mentioned previously.

When various amounts of concentrates, or grain mixture, are added, step by step, to a plentiful supply of roughage, the milk yield of a good cow will be increased until her full capacity is reached. However, the "law of diminishing returns" operates in determining the amount of additional milk that will be secured from the successive additions of concentrates. This means that more additional milk is obtained, per 100 lbs. of concentrates added, from the first few hundred pounds of concentrates fed a year, than from further additions. Constantly decreasing amounts of additional milk are secured, per 100 lbs. of concentrates added, as the level of concentrate feeding is increased.

The feeding of greater amounts of concentrates will not only produce more milk, but will also reduce the amount of hay and other roughage that the cow can consume in a year. Usually, the amount of total hay equivalent, including pasture, saved by each pound of concentrates added per day will range between 0.5 and 0.8 lb. The amount of hay equivalent saved per pound of additional concentrates seems to increase slightly as the level of concentrate feeding is raised, instead of decreasing like the additional yield of milk. This is probably because the total capacity of the cow for holding feed is being approached.

1026. Effect of successive additions of concentrates.—From the results of the cooperative "input-output" experiments, careful estimates were made of the effect produced by successive additions of concentrates to all the roughage cows would consume. Some of these estimates are given in the table on the next page. The cows averaged 1,142 lbs. in weight. Their average yield was 8,919 lbs. of 4 per cent fat-corrected milk in previous lactations when fed concentrates and roughages in accordance with usual dairy practice.

The table shows that as the level

of concentrate feeding is increased, the amount of additional milk secured per pound of concentrate added steadily decreases. About 1.3 lbs. of additional milk (on the 4 per cent fat-corrected basis) are obtained when a small amount of concentrates is added to all the roughage a cow will eat. The amount of additional milk secured per pound of concentrates added steadily falls. When cows are fed an unusually large amount of concentrates, only about 0.3 lb. more milk is secured per pound of additional concentrates.

the latter part of lactation and the dry period for the development of the calf, they lost weight and ran down in condition. On the other hand, when cows had at all times all the good roughage they wanted and were in good flesh at calving, they produced well if fed according to the Haecker standards during the lactation period.

In these studies there were no significant differences between the heavy and light rates of concentrate feeding in the health and reproduction of the cows, except there was more trouble from the cows going "off-feed" when fed heavily on concentrates.

Effect of adding increasing amounts of concentrates to dairy rations

Concentrates fed per year	Hay equivalent fed per year	Estimated yield of 4 % milk	Additional milk per lb. concentrates added	Decrease in hay equiv. per lb. concentrates added
Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
0	11,338	6,438	......	......
450	11,048	7,020	1.3	0.6
900	10,751	7,517	1.1	0.7
1,350	10,447	7,947	1.0	0.7
1,800	10,136	8,317	0.8	0.7
2,250	9,817	8,639	0.7	0.7
2,700	9,492	8,915	0.6	0.7
3,150	9,159	9,156	0.5	0.7
3,600	8,818	9,366	0.5	0.8
4,050	8,471	9,550	0.4	0.8
4,500	8,116	9,708	0.4	0.8
4,950	7,754	9,847	0.3	0.8
5,400	7,385	9,971	0.3	0.8

The table shows that at the lower levels of concentrate feeding each pound of concentrates saved about 0.7 lb. of hay equivalent. At the highest levels of concentrates, the amount of hay equivalent consumed was reduced about 0.8 lb. for each additional pound of concentrates.

At the level of 2,250 lbs. concentrates annually, the cows received a trifle more total digestible nutrients a year than the total advised for maintenance and milk production in the Haecker standards. At the highest level of concentrates, the annual total digestible nutrient intake was about 16 per cent above the Haecker standards.

When cows were fed strictly according to the Haecker standards, with no pasture and no additional feed during

One reason why the law of diminishing returns applies when different levels of concentrates are fed is that at higher levels of concentrate feeding the digestibility of the ration is slightly decreased and the net-energy value decreased still more. (**101**, 78) After making a critical study of the results of the input-output investigations, Reid of Cornell University has recently pointed out that some of the difference in amount of milk produced per pound of added concentrates at the higher levels of concentrate feeding and at low levels can be accounted for by the following: [60] On the low levels the cows lost weight, thus drawing on their bodies for some of the

energy in the milk they produced. At the higher levels they maintained their weights or even gained. The loss in weight on scanty feeding could not continue for successive years, but the milk production would decline to the amount permitted by the nutrient intake.

In the "input-output" studies at certain of the experiment stations some cows were fed all the concentrate mixture they would eat, being brought gradually up to full feeding. For example, in the Pennsylvania tests Holstein and Brown Swiss cows ate an average of 24.6 lbs. concentrates a day throughout the lactation period. The highest amount was 39 lbs. during the peak of production. When thus fed by skilled herdsmen, the cows remained in good health. Though the milk yield was increased somewhat by such heavy feeding of concentrates, the added amount secured per pound of additional concentrates fed was too small to be profitable under any usual conditions.

1027. The most profitable level of concentrates.—Good judgment and experience are necessary to determine the most profitable level of concentrates to feed in any herd, in addition to an abundance of good roughage. The data in the preceding table indicate the approximate amounts of additional milk secured per pound of added concentrates, at various levels of feeding. Also, one must consider the saving in roughage as the amount of concentrates is increased. Any dairyman who is in doubt as to the best level of feeding to use under his local conditions should consult his county agricultural agent or ask for further information from his state agricultural college.

In the corn belt and eastward it is generally most profitable to supply good cows with enough concentrates, in addition to an abundance of high-quality roughage, to meet the recommendations of the feeding standards. When milk is high in price, in comparison with concentrates, it may pay to feed cows of high productive capacity somewhat more concentrates than called for in the higher set of figures in the Morrison standards. In other words, it may pay to feed more concentrates than stated in the grain feeding tables in Appendix Table VIII. Such heavy feeding is advisable only for an experienced dairyman, who watches his cows closely to prevent their going "off-feed" from receiving an excessive amount of concentrates.

At the other extreme, in such regions as some of the alfalfa districts of the West, alfalfa hay may be so cheap in comparison with concentrates that it will be most profitable to feed much less concentrates than called for by the feeding standards. Under these conditions, it may even be most economical to use no concentrates whatsoever, but to feed the cows only hay and other roughage, with pasture in summer. When milk is high in price, it pays even under such conditions to feed some concentrates, in order to secure a larger yield.

When an abundance of high-quality roughage is provided, only a very moderate rate of concentrate feeding may be most profitable and may produce as much or nearly as much milk as more concentrates. For example, in an Ohio experiment cows were fed in winter all the good alfalfa hay they would eat, with corn silage in addition.[61] In summer they had first-class pasture. When fed about as much grain mixture as advised in Appendix Table VIII for "very liberal feeding of good roughage," cows produced, on the average, fully as much milk as cows fed considerably more grain mixture. First-calf heifers placed on the moderate rate of concentrate feeding tended to yield less milk the first year than those fed more liberally, but in the following lactations they produced more than the cows fed larger allowances of grain mixture.

1028. Milk production on roughage alone.—Several experiments have been conducted, especially by western experiment stations, to determine how much milk and fat good cows would yield on roughage alone.[62] The actual production on such rations will differ considerably, depending on the quality of the hay or other roughage, the size and productive capacity of the cows, and on whether a

phosphorus supplement is provided to ensure an ample supply of this mineral nutrient.

From a study of the results of such experiments conducted by the United States Department of Agriculture and western state experiment stations, Woodward reached the following conclusions.[63] On a ration of only good alfalfa hay, plus a phosphorus supplement if needed, good cows milked twice a day will yield about 0.8 lb. of butterfat a day, as an average for the lactation period, or approximately 250 lbs. of fat a year. When corn silage is fed in addition to alfalfa hay, the annual yield of fat will be increased to about 275 lbs. If the cows have first-class pasture in addition during the growing season, it is possible to increase the yield to 300 lbs. of fat a year. He states that these yields should be considered maximum, rather than average, because the quality of both the hay and the pasturage was somewhat above average in the experiments upon which the estimates were based.

Because of the widespread use of hay-crop silage for dairy cattle, it is important to note that higher milk production cannot apparently be maintained on hay-crop silage alone than on hay alone. In a recent Indiana test Holsteins that had been producing 45 to 50 lbs. of milk a day, dropped rapidly to 25 to 30 lbs. when fed only alfalfa silage.[64]

In the southern states good pasture can, with proper fertilization and good management, be provided during most of the year. Under such conditions higher milk yields can be secured without concentrates than in colder regions where cows cannot be pastured in winter. For example, at the West Tennessee Station, Jersey cows fed no concentrates averaged 5,883 lbs. milk and 342 lbs. fat a year.[65] They were provided with all-year pasture, crimson clover or crimson clover and ryegrass being used from late fall until spring. In addition they were fed alfalfa hay and silage, thus having an abundance of good roughage at all times. Though good production was thus secured without concentrates, other cows fed an average of 1,933 lbs. concentrates a year produced 980 lbs. more fat-corrected milk.

1029. Liberal feeding necessary for good production.—Good milk production cannot be secured unless cows have an abundance of feed. When concentrates are so high in price in comparison with roughage that it is wise to feed less concentrates than normal, special care must be taken to keep the cows filled up with high-quality roughage. Otherwise, production will be so low that the net returns will be seriously reduced.

The financial benefits from the proper feeding and care of good cows are shown in a striking manner by an Indiana demonstration.[66] Cows that were of good type, but which had been low producers, were selected from farms where the cattle had not been well fed. They were then brought to the Station and properly fed and cared for. On the Indiana farms these cows had produced an average of only 5,064 lbs. milk, but in the Station herd the following year they averaged 8,662 lbs. Though the annual feed cost per cow was 65 percent higher than when they had been fed poorly, the investment in proper feeding and good care brought 74 percent greater net return over feed cost. Just as striking proofs of the benefits from proper feeding and care are furnished by numerous instances in the records of cow-testing associations, where dairymen have greatly increased their net income by adopting improved methods.

1030. Feeding only a limited amount of roughage.—Some producers of market milk on high-priced land near the large cities follow the plan of limiting the amount of roughage and feeding an unusually liberal amount of concentrates. They do this because they wish to keep the maximum number of cows on their farms, and they can more readily provide additional feed in the form of purchased concentrates than in the form of purchased roughage. In other dairy districts, the supply of home-grown roughage may occasionally be seriously reduced because of drouth.

Under such conditions, the problem

always arises as to whether it is more economical to buy hay or to purchase additional concentrates as a substitute for part of the usual roughage allowance. The net energy values of concentrates and of hay provide the best basis for making a decision. Comparisons based on total digestible nutrients will give somewhat too high a value to hay, if there is already available on the farm enough good-quality roughage to supply sufficient bulk and enough vitamins.

[illegible] concentrate mixture [illegible] about 70 to 75 therms of [illegible] energy per 100 lbs., while good-quality hay will supply 40 to 45 therms per 100 lbs. On the average, it will take about 1.75 lbs. of good hay to provide as much net energy as is furnished by 1.0 lb. of a good dairy concentrate mixture. On this basis, such a concentrate mixture would be worth 1.75 times the price of good hay as a substitute for part of the roughage usually fed to dairy cows.

It is wise to feed cows at least half the normal amount of roughage, instead of replacing any larger proportion with concentrates. Good roughage is usually the chief source of carotene in winter rations. Also, a certain amount of good roughage seems to be necessary for ruminants to digest and utilize their feed normally. (45)

Several experiments have proved that if cows are fed only a small amount of hay and no other roughage, but with a liberal amount of a concentrate mixture, bad results follow.[67] The milk yield usually declines decidedly, the fat percentage falls greatly, and the cows frequently go "off feed." In some experiments the fat test has declined somewhat when as much as 8 lbs. of hay a day has been the only roughage. Finely-ground hay has a more pronounced effect than the same weight of long hay. This effect is very marked and the results may be serious if only 2 to 4 lbs. of hay are fed, with no other roughage. In Wisconsin trials the milk in some cases had less than 1 per cent fat.

Bulky concentrates, such as brewers' dried grains, dried beet pulp, or dried citrus pulp, were not a satisfactory substitute for all the roughage in Florida experiments.[68] A very marked decline in fat test has been reported in some instances when cows have been pastured on very young cereals, without other roughage.

1031. Including alfalfa hay in concentrate mixture.—If plenty of ordinary roughage is available on the farm, there is no advantage in adding ground alfalfa hay or alfalfa pellets to the concentrate mixture. The added alfalfa is still hay, and not a concentrate.

The experiments summarized previously show that milk production is not increased by this addition, and it is necessary to feed enough more of such a mixture to offset the lower amount of total digestible nutrients and net energy in hay. (459) When 20 or 30 per cent of alfalfa meal or pellets has been included in a concentrate mixture, the added alfalfa has been worth only about two-thirds as much as the usual concentrate mixture.

1032. Self-feeding cows.—Although the self-feeding method is widely used in swine feeding and is also often employed in the fattening of cattle and lambs, self-feeding a concentrate mixture is not satisfactory for dairy cows. Experiments at the Illinois and Virginia Stations show that when cows are self-fed grain and other concentrates they will eat a much greater amount than they need, thus making the method decidedly uneconomical.[69] If self-fed different concentrates, free-choice, they will also eat a much larger proportion than necessary of the protein-rich feeds.

A mixture of concentrates and coarsely ground or chopped hay can be self-fed to cows, the proportion of hay depending on the milk production.[70] However, the milk yields of the various cows in a herd differ widely, and those yielding a small amount of milk need much less concentrates than the cows producing at a high level. Self-feeding the same mixture of concentrates and hay to all the cows does not adjust the concentrate intake to the actual needs of the individual cows.

1033. Mineral requirements.—It has been shown in Chapter VI that in most regions common salt is the only mineral that is usually deficient in rations that are otherwise satisfactory for cattle.[71] Since milk is very rich in calcium and phosphorus, it may sometimes be necessary to feed dairy cows a supplement furnishing one or both of these minerals, as advised later. In the areas where there is a deficiency of one of the trace minerals, the lack should be corrected, as explained in Chapter VI.

1034. Salt.—Except in a very few areas where the forage has an unusual content of common salt, salt should be supplied regularly to cattle, as advised in Chapter VI, or they will not thrive. (**140**) Probably the best plan, in the case of cows being fed the usual amount of a concentrate or "grain" mixture, is to mix 1.0 lb. of salt with each 100 lbs. of concentrates, and then in addition provide salt in a salt box or by the use of salt blocks, so the cows can always have access to it. Mixing some salt with the grain mixture tends to make it more palatable and also insures that the cows get salt each day. Most of the formula dairy feeds contain added salt.

Extensive experiments on the salt needs of dairy cattle have been conducted recently by Smith and associates of Cornell University.[72] When no salt was supplied dairy cows, they soon showed marked craving for it. However, appetite, milk production, and live weight were not affected for 5 months or more. Then cows suffered greatly from the lack. The milk yield fell, the cows lost much weight, and death could occur. Recovery was rapid when salt was supplied.

The experiments showed that about 1 ounce per head daily met the requirement for cows producing up to 12,000 lbs. of milk a year. When cows were fed the usual amount of concentrates, this need was met nicely by including 1 per cent of salt in the concentrate mixture. When cows fed a concentrate mixture containing no salt were allowed free access either to block salt or to granular salt in a weather-protected box, they consumed about twice as much granular salts as of block salt. However, those getting block salt took enough to meet their needs.

1035. Phosphorus requirements.—Dairy cows usually receive sufficient phosphorus, if they are fed enough concentrates to meet the recommendations of the feeding standards and if the concentrate mixture contains at least 25 per cent of such high-phosphorus protein supplements as wheat [illegible] seed meal, or linseed meal. The [illegible] re- tion may be when the roughage [illegible] on soil decidedly lacking [illegible] the

A ration of roughage alone [illegible] only roughage and farm grain is apt to be deficient in phosphorus, especially for high-producing cows. Therefore a phosphorus supplement should be added to such rations, unless one is sure that the roughage has been grown on a soil well supplied with phosphorus and that it actually has a good phosphorus content. (**150**) Accordingly, a phosphorus supplement should usually be supplied to cows on pasture which are fed no concentrates, or when they are fed only cereal grain on pasture.

A phosphorus supplement is especially needed when a considerable part of the ration consists of a feed which is very low in phosphorus, such as beet pulp, molasses, cereal straw, or cottonseed hulls. The effects of a deficiency of phosphorus have been described in Chapter VI.

When there may possibly be a deficiency of phosphorus, it can readily be prevented by allowing the cows access to one of the mineral mixtures previously recommended, or else by adding 20 to 40 lbs. of bone meal or some other safe phosphorus supplement to each ton of concentrate mixture. (**186**) A phosphorus supplement containing a dangerous amount of fluorine should not be used. (**169**) If the concentrate mixture already has at least 0.5 per cent phosphorus, there is no need of adding a phosphorus supplement to it.

The amounts of phosphorus advised in the Morrison feeding standards (Appendix Table III) are based on the investigations of Huffman and associates

at the Michigan Station.[73] By computation, it will be found that the ration of a 1,200-lb. cow producing about 30 lbs. of milk a day should contain, on the air-dry basis, about 0.23 per cent phosphorus, and the ration of a cow yielding 60 lbs. of milk, about 0.26 per cent phosphorus. From the data in Appendix Table [illegible] one can determine the approximate percentage of phosphorus a particular ration will furnish, if the roughages have been grown on soil fairly well supplied with phosphorus. In computing the percentage of phosphorus in a ration containing silage, the silage should be reduced to an air-dry basis by dividing the weight fed by 3 and multiplying the phosphorus percentage shown in the [illegible] by 3. For example, 30 lbs. of well-matured corn silage of average composition, containing 0.07 per cent phosphorus, are approximately equal to 10 lbs. of air-dry silage containing 0.21 per cent phosphorus.

In West Virginia experiments Holstein heifers producing 20 to 30 lbs. of milk a day showed no serious evidences of phosphorus deficiency when receiving somewhat less phosphorus than recommended by the Michigan investigators.[74] However, it was believed that they were on the border line of deficiency, as they showed a lack of appetite and certain other symptoms.

1036. Calcium requirements.—In spite of the fact that milk contains a slightly greater quantity of calcium than of phosphorus, there is much less apt to be a lack of calcium in dairy rations than of phosphorus. This is because even non-legume roughages generally contain more calcium than phosphorus, and all legume roughages are very rich in calcium. Also, cows can apparently utilize the calcium in their feeds somewhat more efficiently than the phosphorus.

Dairy cows will receive plenty of calcium when at least one-quarter of their roughage, on the dry basis, is legume hay or other legume forage. Even when they receive little or no legume forage, the supply of calcium is not apt to be deficient if they are fed plenty of roughage of good quality, unless the forage is raised on soil very low in this mineral. When there is no legume roughage in the ration, it is probably wise to supply a calcium supplement as insurance against any possibility of deficiency, unless the non-legume roughage has been raised on soil well supplied with calcium. When such a phosphorus supplement as bone meal is fed, this will supply both phosphorus and calcium.

Calcium may readily be supplied by including 20 to 30 lbs. of ground limestone or other calcium supplement in each ton of the concentrate mixture, or by letting the cows have access to one of the mineral mixtures suggested in Chapter VI. (186) Unless the deficiency of calcium is serious, it is best to use not more than 20 lbs. per ton, or the palatability of the concentrate mixture may be lessened. Also, recent New Hampshire experiments have shown that the digestibility of protein may be decreased if too much calcium supplement is fed.[75]

In the Morrison feeding standards, the author has followed the recommendations of the special committee of the National Research Council concerning the amounts of calcium for dairy cattle.[25] It will be noted that 8 grams of calcium per day are recommended for the maintenance of a 1,000-lb. cow and 1 gram in addition for each pound of milk produced. An additional amount is advised for the last part of the pregnancy period. It will be found that most dairy rations which are satisfactory otherwise will provide more calcium than the minimums considered necessary.

Experiments have proved that good dairy cows are not injured when fed for long periods on rations having somewhat less calcium than advised in the standards. In Wisconsin experiments good cows were fed a concentrate mixture low in calcium, with timothy hay and corn silage for roughage in winter and with grass pasture in summer.[76] The winter rations had only about 0.20 per cent calcium on the dry basis. Other cows received a calcium-rich ration, with legume hay and pasture in place of the timothy hay and grass pasture, and with a mineral supplement furnishing addi-

tional calcium. The milk production was just as good on the low-calcium ration. Also, when some of the cows were slaughtered after 3 years on these rations, the skeletons of the cows fed the low-calcium rations were normal, containing as much calcium as those which had received the calcium-rich ration.

In Minnesota trials no serious results occurred when cows were fed for long periods on a ration having only 0.12 per cent calcium.[77] In order to reduce the calcium to this very low level it was necessary to feed only 6 to 7 lbs. a day of timothy hay that was unusually low in calcium. In similar experiments by the United States Department of Agriculture it was concluded that milk cows do not need more than 0.16 per cent calcium in the dry matter of the ration and that growing heifers require slightly less.[78]

Florida and Louisiana experiments show that where the soil is unusually deficient in calcium, dairy cows fed only non-legume roughage, even of good quality, may suffer seriously from a lack of the mineral, unless a calcium supplement is supplied.[79] In the Louisiana trials cows fed such a ration, very low in calcium but having adequate phosphorus, showed stiffness on walking, and in some cases humped back, bent hind legs, swollen leg joints, and constant licking. Some of the cows aborted, though the herd was free from brucellosis, and often the calves were born dead or very weak.

In the Florida experiments the cows, which had a liberal amount of concentrates, did not show the emaciation common in phosphorus deficiency. However, the milk yield was very low and some cows had suffered broken bones with no apparent cause. In both series of experiments the bad results were prevented when a calcium supplement was provided.

1037. Losses and storage of calcium and phosphorus.—Extensive experiments have shown the rather surprising fact that even when high-producing cows are fed ideal rations, rich in calcium and phosphorus, they frequently put more of these minerals into their milk at the height of milk production than they can assimilate from their feed.[80] During this period they therefore draw on the stores of these minerals in their skeletons. When they are producing less milk and especially when they are dry, they are able to rebuild their stores of calcium and phosphorus. It is therefore important to supply plenty of these minerals during the dry period.

To find whether the process of drawing on the mineral reserves during high milk production was injurious, continuous metabolism experiments over the entire lactation periods were conducted with good dairy cows by Ellenberger and associates at the Vermont Station and by Forbes and colleagues at the Pennsylvania Station.[81] The cows, which [illegible] 9,000 to 15,000 lbs. of milk a year, [illegible] calcium and phosphorus during the first part of the lactation period, when their yields were largest. However, in nearly all cases they stored sufficient of the minerals later so that by the next calving time the losses were more than replaced. This was true even when the cows were fed no legume hay, but only [illegible] timothy hay and corn silage as the roughages. Adding bone meal, ground limestone, or a mixture of the two tended to lessen the losses of minerals during the early part of the lactation period and to result in a greater storage for the entire year. There was, however, no proof that the addition of these supplements improved the health or production of the cows.

1038. Adding calcium or phosphorus to good rations.—Experiments have been conducted by several stations to determine whether or not there would be any benefit from adding a phosphorus and calcium supplement to good dairy rations.[82] In these experiments one group of cows has been fed a well-balanced ration, including plenty of good roughage and the usual amount of a concentrate mixture of the common type, with no mineral supplement except common salt. Another group has received the same ration, except that a mineral supplement, such as bone meal, has been added to supply additional phosphorus and calcium. In some cases a mineral mixture

has been used, containing such supplements as bone meal and limestone.

Unless the roughage was unusually low in phosphorus or in calcium, in most cases there has been no appreciable benefit from the use of these mineral supplements. This has been true even when little or no legume hay or other legume roughage has been fed. These experiments have definitely proved that the use of phosphorus or calcium supplements for milk cows is advisable only under the special conditions stated in the previous paragraphs.

1039. Trace minerals.—Except in the areas where there is a deficiency of one of the trace minerals—iodine, cobalt, copper, iron, or manganese—there is no benefit from feeding a trace mineral supplement, or in using trace-mineralized salt instead of common salt.[88] Detailed information on each of these minerals and on the way in which any deficiency can be corrected has been given in Chapter VI.

As stated there, the claims which have sometimes been made that manganese or other trace mineral supplements will prevent or cure brucellosis, have been proven false. (**180**) Studies have been conducted by the Wisconsin Station to determine whether a lack of trace minerals may be involved in repeat-breeding cows, which require repeated services to get them in calf.[84] It was concluded that trace minerals had little, if any, direct relationship to this problem.

Rations unusually low in manganese, having less than 4.5 milligrams per pound, produced normal growth of dairy heifers, but on this very low level of manganese they did not come into heat at as early an age as normal, and were slightly slower to conceive. Most ordinary dairy rations contain much more manganese than this.

1040. Vitamin requirements.—Under any usual conditions vitamin A and vitamin D are the only vitamins that need be considered in the feeding of dairy cows. (**198, 199**) Generally, there is no lack even of these vitamins when dairy cows are on pasture during the grazing season and are fed good roughage during the rest of the year, including a reasonable amount of satisfactory field-cured hay. The requirements of dairy cows for vitamin A and vitamin D are considered in detail in articles which follow. The vitamin requirements of dairy calves and heifers and also of dairy bulls are discussed in a later chapter.

The B-complex vitamins are synthesized by bacteria in the fermentations which normally occur in the rumen of cattle. (**209**) Except in the case of very young calves, ample amounts of these vitamins are therefore provided by the content in the feed plus the amounts synthesized by bacterial action. In Minnesota and New York experiments there was no advantage in adding yeast, which is rich in these vitamins, to a normal ration for dairy cows.[85] To ensure a plentiful supply of B-complex vitamins, brewers' dried yeast or some other B-complex supplement is often included in milk replacers for dairy calves weaned from milk at a very early age. (**1119**)

Sometimes when cattle are in a very run-down condition because of inadequate rations or because of disease or parasitic infection, the addition of yeast or B-complex vitamins may stimulate the appetite and be beneficial.[86] In such cases the normal bacterial action has probably not been taking place in the rumen.

Like other farm animals, dairy cows undoubtedly require ascorbic acid (vitamin C), but sufficient amounts are normally synthesized or formed in their body tissues. (**224**) When ascorbic acid is present in the feed of cattle, it is destroyed in the fermentations that take place in the rumen. Symptoms of scurvy, the disease caused by a deficiency of ascorbic acid, have been reported in dairy cows and calves in Michigan.[87] The condition of the cattle improved when they were treated by feeding chlorotone or by hypodermic injections of ascorbic acid.

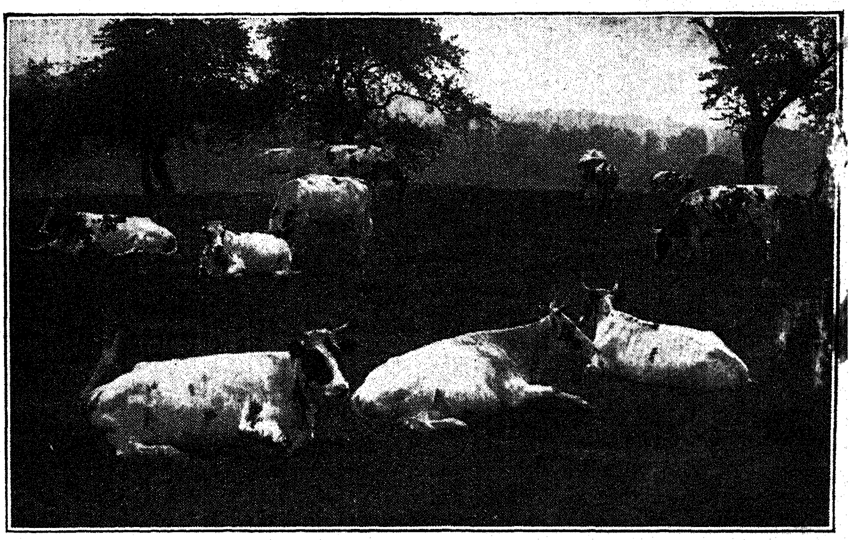
Advertising claims are made that the feeding of wheat germ oil or other vitamin E supplements aids in preventing or curing sterility in cattle. With reference to this matter, the author

agrees fully with the statement of a special committee of the National Research Council in their report on Recommended Nutrient Allowances for Dairy Cattle: "It appears that natural feed stuffs generally furnish adequate amounts of vitamin E to supply the small amount needed." [25]

Sometimes muscular degeneration, or dystrophy, and other symptoms occur in calves fed restricted rations, without a normal amount of milk or plenty of good roughage.[88] (223) Such trouble can generally be prevented by the use of a vitamin E supplement. In an Iowa experiment there was no benefit from adding a vitamin E supplement to a normal ration for dairy calves.[89]

1041. Vitamin A and carotene.— Dairy cows must have ample vitamin A to remain healthy and to produce thrifty calves, as has been shown in Chapter VII. Fortunately, plentiful amounts are furnished when cows have good pasture during the growing season and are fed a reasonable amount of good hay, with or without silage, during the barn-feeding period. These roughages supply liberal amounts of carotene, which animals readily convert into vitamin A in their bodies. Also, when animals are on good pasture, they store considerable vitamin A in their liver and other tissues. This helps to meet their needs whenever the supply in the feed may be scanty.

Only when special vitamin A supplements are fed, for instance in the case of young calves, do cattle normally secure any of their vitamin A needs from actual vitamin A in their feed, because all feeds of plant origin are believed to contain none. The vitamin A requirements are therefore commonly stated in terms of carotene.



CATTLE ON GOOD PASTURE STORE VITAMIN A

If dairy cows are on good pasture during the grazing season, they will start the barn-feeding period with a considerable store of vitamin A in their bodies.

In the Morrison feeding standards the carotene allowances provide 40 milligrams of carotene daily per 1,000 lbs. live weight for maintenance, and an additional amount of 30 milligrams daily for a 1,000-lb. cow during the last 2 to 3 months of pregnancy. These are the same amounts as recommended in the report by the special committee of the National Research Council, which has been referred to previously.[25] It is be-

lieved that these amounts are sufficient for normal yields of milk and satisfactory reproduction. As is shown later, the vitamin A value of the milk is increased considerably when the rations of cows provide far larger amounts of carotene or of vitamin A. (**1043**) The carotene and vitamin A requirements of calves are discussed in Chapter XXVII.

When dairy cows are fed a liberal amount of good-quality roughage, they will usually receive much more than the minimum amounts of carotene that have been mentioned. For example, 100 milligrams of carotene will generally be furnished by only 5 lbs. of field-cured legume hay of the best quality or by 14 lbs. of fairly good legume or mixed hay. The same amount of carotene will be provided by 20 lbs. of corn silage of average quality. (Appendix Table V.)

A fairly liberal supply of carotene is advisable for dairy cows during the latter part of pregnancy, because it increases the vitamin A store in the new-born calf and also increases the vitamin A value of the colostrum milk. (**270**) This tends to make the calves more vigorous and thrifty, and to lessen trouble from scours or other diseases.

The amounts of carotene needed by dairy cows for health and successful reproduction have differed somewhat in experiments to determine the minimum requirements.[90] Guernseys and Jerseys need more carotene per 1,000 lbs. live weight than do Holsteins, probably because they convert carotene into vitamin A less efficiently. It is believed that the amounts of carotene recommended in the standards are ample, even for these breeds.

It has been explained previously that feeding a large proportion of soybeans in the concentrate mixture for dairy cattle decreases the utilization of carotene or vitamin A. (**792, 798**) However, this is not of practical importance unless the ration is borderline in content of carotene or vitamin A.

1042. When may deficiencies of vitamin A occur?—It is important to know the conditions under which a deficiency of vitamin A may occur in the practical feeding of dairy cows. Fortunately, animals have a large capacity to store vitamin A in their bodies when the supply is very liberal. (**192**) If dairy cows are on good pasture during the grazing season, they may therefore have a sufficient store of vitamin A to enable them to get through the usual barn-feeding season without decided injury on a ration low in carotene. For example, in Oregon trials dairy cows which had been on excellent pasture in summer had normal calves in spring, even when fed poor-quality hay as the only source of carotene throughout the winter.[91]

However, it is not wise to feed rations low in carotene during all the winter, even when cows have been on pasture in summer. Unless they have a large store of vitamin A in the fall, it may be depleted within 2 to 3 months on a deficient ration.

That straw produces disastrous results when fed as the only roughage to dairy cows over long periods was shown in extensive Wisconsin experiments.[92] Cows fed wheat or oat straw as the sole roughage, with no pasture in summer, became unthrifty and aborted or had weak or blind calves. On the other hand, the results were satisfactory with well-cured corn fodder as the only roughage. The poor results were due to the deficiency of vitamin A and also to a lack of calcium. When these were added in later trials, reproduction was normal. It has been shown previously that the results were also disastrous in other experiments in which poor-quality timothy hay was fed for long periods as the only roughage. (**564**)

In Oklahoma trials prairie hay of good quality furnished ample carotene for dairy cows when it was fed liberally.[93] When only one-half the usual amount of hay was fed, with dried beet pulp replacing the rest of the hay, the supply of carotene was insufficient. In long-time New Mexico experiments a ration of whole hegari fodder (a grain sorghum) and cottonseed meal was so low in carotene that reproductive failure resulted and some of the cows died.[94] In North Carolina trials, including 26 per

cent of yellow corn in a carotene-poor ration of cottonseed hulls and cottonseed meal did not provide sufficient carotene.[95] Including 20 per cent of good soybean hay in the ration furnished enough carotene, but the same amount of poor-quality alfalfa hay was inadequate.

In general, it seems safe to conclude that if cows have reasonably good pasture in summer and if at least one-half their roughage during the barn-feeding season is good-quality hay or silage, there will be no deficiency of vitamin A.

1043. Effect of breed on vitamin A value of milk and butterfat.—Part of the vitamin A value of milk and butterfat is due to the nearly colorless vitamin A which the cow has formed from the yellow carotene in her feed. Part is due to carotene which she has transferred unchanged into her milk.

Guernseys and Jerseys do not convert into vitamin A so large a proportion of the carotene they assimilate as do cows of the other breeds. They therefore secrete more carotene and less vitamin A in their milk, and this makes it yellower in color. Likewise, their body fat and even skin secretions are colored yellow by carotene. Holsteins, Ayrshires, Brown Swiss, and Shorthorns convert most of the carotene into vitamin A, and therefore their milk and body fat have but little yellow color. If Guernseys or Jerseys are fed a ration low in carotene for a long time, their milk will also have little yellow color.

Experiments have shown that when cows of the various breeds are fed similar rations, there is no appreciable difference in the total vitamin A value of the yellow-colored butterfat from Guernseys or Jerseys and that of the much paler butterfat from cows of the other breeds.[96] As Guernsey and Jersey milk is normally considerably richer in fat than Holstein, Ayrshire, Brown Swiss, or Shorthorn milk, it will have a correspondingly higher total vitamin A value per quart, if the cows are fed similar rations.

1044. Effect of ration on vitamin A value of milk and butter.—Over any long period, the vitamin A value of milk and butterfat depends entirely on the amount provided in the feed. Temporarily, a cow can draw on her body store for some of it. If cows are continuously fed rations low in carotene, not only will they themselves be injured, but also their milk will be very low in vitamin A value. This is very important, both from the standpoint of human nutrition and in raising dairy calves.

Experiments have shown that to secure the maximum vitamin A value in milk, a much larger amount of carotene must be supplied in the feed than is necessary for the well-being of the cow herself. For example, in Indiana experiments 460 milligrams of carotene were needed in the ration to secure the maximum vitamin A value in the milk.[97] As shown previously, this is about 5 times as much as is needed for the well-being of the cows and for successful reproduction.

Under practical conditions milk has the maximum vitamin A value when the cows are on good pasture.[98] During the barn-feeding season the vitamin A value is less, but it may be kept reasonably high when good-quality hay and silage are fed. Since well-preserved hay-crop silage has more carotene than does corn or sorghum silage, it aids in maintaining a high vitamin A value and also yellower color in milk. (437) It has been shown previously that the feeding of soybeans or of soybean hay containing a considerable amount of soybeans decreases the vitamin A value of the milk. (792)

A very extensive study of the vitamin A value of butter and milk in various states has recently been made by the United States Department of Agriculture in cooperation with various experiment stations.[99] It was found that 4 per cent milk produced under winter-feeding conditions had an average vitamin A potency of 1,140 International Units per quart, and summer milk a potency of 1,800 International Units. However, much milk produced when cows are on first-class pasture has 2,000 to 3,000 Units per quart. The average potency throughout the year was 1,530 International Units. The average potency of

creamery butter was about 15,000 International Units per pound, with an average of approximately 18,000 Units for summer butter and 11,200 for winter butter.

When cows are fed adequate rations, only a small percentage of the vitamin A value of their feed is transferred into their milk. In various experiments the recovery of vitamin A value in the milk has not been more than 2 or 3 per cent of that in the feed.[100] If rations are fed that are very rich in carotene, the percentage recovery in the milk is much lower.

1045. Effect of adding a vitamin A supplement to good rations.—When dairy cows are fed plenty of good hay and silage, supplying still more vitamin A or carotene by the use of a special vitamin supplement will increase the vitamin A potency of the milk somewhat. However, it is doubtful whether it will generally increase the yield of milk or fat, or at least increase it enough to warrant the expense.

In Florida, Idaho, and Wisconsin experiments the yield of milk or fat was not increased by adding to good rations over 1,000,000 International Units of vitamin A per head daily in the form of shark-liver oil, which is exceedingly rich in the vitamin.[101] In fact, the shark-liver oil tended to reduce the yield in the Wisconsin trials. In certain other experiments the addition of shark-liver oil or other vitamin A supplements has slightly increased the milk yield.[102]

Cod-liver oil should not be used as a vitamin supplement for dairy cows, because it decidedly lowers the richness of the milk. (**207**)

1046. Vitamin D.—Although dairy cows require vitamin D, adequate amounts are generally supplied by sun-cured roughages or are provided by the action of sunlight. However, advertising claims are often made that dairy cows are greatly benefited by vitamin D supplements.

After considering all the data on the vitamin D requirements of dairy cows, the author agrees fully with the conclusions of the special committee of the National Research Council in their report on *Recommended Nutrient Allowances for Dairy Cattle.*[25] They state: "It is probable that under usual farm conditions adequate amounts of vitamin D are supplied by sun-cured roughages or provided by the action of sunlight."

Cows which are on pasture during the summer grazing season start the barn-feeding season with a considerable store of vitamin D in their bodies. This is due almost entirely to the anti-rachitic effect of the ultra violet rays in the sunlight, as green pasture forage has little or no vitamin D. (**204**)

In South Dakota experiments, in order to produce any symptoms of vitamin D deficiency in dairy cows, it was necessary to keep them entirely out of the sunlight and to feed abnormal rations, containing no field-cured hay or other sun-cured roughage.[103] Adding as little as 2 lbs. per head daily of good field-cured alfalfa hay to such rations cured cows showing severe vitamin D deficiencies, even though they were never exposed to sunlight.

Even when cows had no exposure to sunlight and were fed a ration devoid of vitamin D, with molasses beet pulp in place of hay, high-producing cows did not show definite symptoms of vitamin D deficiency until after about 4 months in the South Dakota experiments. Cows giving 25 to 40 lbs. of milk a day did not become depleted of their store of vitamin D until after 6 to 8 months.

In these experiments it was found that if cows suffering from a vitamin D deficiency produced by these abnormal conditions were continued on the deficient ration, but exposed to sunlight, they recovered rapidly. This was true even in the fall and winter, when sunlight has less anti-rachitic effect. For example, a cow showing severe symptoms of deficiency in late October was restored nearly to normal in 6 weeks when continued on the deficient ration but exposed to the late fall and early winter sunlight.

There is insufficient information as yet to warrant definite conclusions con-

cerning the minimum amounts of vitamin D required by dairy cows. Wallis found that a cow which had developed definite symptoms of vitamin D deficiency on the abnormal ration without sunlight, improved greatly when 3,000 International Units of vitamin D were added.[104] Even oat straw had 748 International Units of vitamin D per pound in the South Dakota studies. The feeding of 8 to 10 lbs. of most field-cured hay would supply 5,000 to 6,000 International Units of vitamin D. Barn-dried hay and wilted hay-crop silage have been found to supply enough vitamin D to protect calves against rickets. (**204**)

The vitamin D requirements of dairy calves are discussed in Chapter XXVIII. (**1118**) As stated there, under certain conditions, a vitamin D supplement should be added to the rations for dairy calves.

1047. Adding vitamin D supplements to ordinary rations.—In a Massachusetts experiment there was no benefit from adding irradiated yeast as a vitamin D supplement to the ration of dairy cows maintained under good practical conditions.[105] Similarly, in an Ohio trial under farm conditions, the exposure of dairy cows to the light from ultra-violet lamps, in addition to normal exposure to sunlight, was not beneficial to the cows, though it increased the vitamin D content of the milk.[106]

In a long-time Vermont experiment dairy cattle were fed for consecutive generations on good, early-cut timothy hay in comparison with late-cut timothy hay.[107] Both groups received silage and normal amounts of concentrates lacking vitamins A and D. The cattle were not pastured during the summer, but were turned out for a short time daily throughout the year for exercise. During the growing season they were fed a limited amount of green soiling crops. Some of the cattle fed each kind of hay received a vitamin A and D supplement (cod-liver oil concentrate).

Even though these cattle were exposed much less to sunlight than if they had been on pasture, no animals showed any deficiency of vitamin D, even on the poor-hay ration without any vitamin supplement. Also, there were no indications of a deficiency of vitamin A. The addition of the vitamin supplement was of no benefit to the cattle fed the good-quality timothy hay, and of only slight benefit to those fed the poor hay. Until the heifers were a year old, the good hay produced definitely better results than the poor hay.

In a New York trial, feeding a vitamin D supplement to dairy cows for 8 weeks before calving, increased the vitamin D content of the blood of the cows, but did not consistently change the store in the calves at birth.[108] The feeding to dairy cows susceptible to milk fever of extremely large doses of vitamin D as a preventive, for a very few days before calving, is discussed in the next chapter. (**1086**)

1048. Adding various mineral and vitamin supplements.—Claims are sometimes made that the addition of various mineral and vitamin supplements to good dairy rations will prevent or cure brucellosis (Bang's disease) and lessen other breeding troubles. An extensive experiment was conducted at the Wisconsin Station to find whether the ravages of Bang's disease could be lessened by rations which were ideal and contained an abundance of legume forage, with mineral and vitamin A and D supplements in addition.[109] Cattle raised on such a ration showed no more resistance to the disease than others which were fed ordinary rations that provided sufficient protein but that had no legume forage and no mineral or vitamin supplements. In other experiments trace mineral supplements have been ineffective as preventives of brucellosis. (**180**)

The effect of adding vitamin A or vitamin D supplements to good dairy rations has been discussed previously in this chapter, and the use of kelp and mixtures containing kelp has been considered in Chapter XXIII. (**977**) In most other experiments there has been no benefit from adding complex mineral and vitamin supplements to the ordinary types of good dairy rations.[110] Sprouted oats, sometimes recommended as a pre-

ventive of breeding difficulties, had no apparent beneficial effect in Nebraska tests with dairy cattle.[111]

1049. Water.—Often the production of cows is lessened because they cannot readily get plenty of water. There is no greater folly in dairying than this, for feed and labor are expensive in comparison with water. Of all farm animals, dairy cows in milk require the greatest amount of water in proportion to their size, because water forms about 87 per cent of the milk they yield.

The amount of water cows will drink depends on their size, the yield of milk, the air temperature and humidity, and the amount of water in the feed they eat.[112] From 100 lbs., or 12.5 gallons, up to 120 lbs., or 15 gallons, per head daily is an average amount for a herd, including both cows in milk and dry cows. Cows producing 100 lbs. of milk a day may drink 300 lbs. of water a day or even more.

Experiments have shown that providing water by means of automatic drinking bowls, so the cows can drink whenever they wish, increases the milk yield of good cows 3.5 to 4.0 per cent over watering twice daily, and 6 to 11 per cent over watering once daily.[113] It also saves labor and aids in providing a more sanitary supply of water. When drinking bowls are not used, high-producing cows should be watered at least twice a day, and in severe weather they should be watered indoors, if possible. There is less benefit from the use of drinking bowls for low producers than for high producers. Cows watered with water bowls drank an average of about 10 times each 24 hours, and about one-third of the water was drunk during the night, from 5 p.m. to 5 a.m.

It was found on 500 Maine farms that the milk yield of cows watered with drinking cups was 19 per cent greater than in herds watered out of doors and 9 per cent more than in herds watered from a tub in the barn.[114] The greater production secured with drinking cups was undoubtedly due partly to the facts that the owners were more progressive dairymen, had better cows, and fed and cared for them more efficiently in other respects.

When cows drink from an outdoor tank, it is probably wise to warm the water during very cold winter weather, so they will drink sufficient for their needs. However, in a Washington test the production was not increased by warming the water for one group of cows, in comparison with another group receiving water which had a temperature of about 32° F. most of the time.[115]

Care should be taken to keep drinking bowls and tanks in a sanitary condition by frequent cleaning. This is an important point that is often overlooked.

Including both the water in their feed and the water they drink, cows consume from 3.4 to 5.5 lbs. of water for each pound of milk they yield. On a ration of silage, hay, and concentrates, they will drink in ordinary weather 2.3 to 4.4 lbs. of water per pound of milk produced, in addition to the water in their feed.

In hot weather cows may drink 80 per cent more than in moderate weather. However, in a California test cows did not drink much more water at air temperatures up to 80° F. than at a lower temperature, when the air humidity and movement were kept constant.[116] In weather down to freezing temperature, cows drink about the same amounts as in moderate weather, if the water is not too cold and is comfortably accessible.

The feeding of a ration very high in protein considerably increases the water consumption. Adding any succulent feed to a dry ration decreases the water drunk, but not the total intake of water. If roots are fed in place of silage, cows drink less water, but the total water intake in feed and water drunk is greater on the root rations.

1050. Antibiotic feed supplements.—Iowa, Kansas, and Louisiana experiments have shown that there is no benefit from adding an antibiotic feed supplement to rations for dairy cows.[117] Neither the milk production nor the fat percentage has been increased. In Wisconsin tests feeding an antibiotic supple-

ment was not an aid in getting hard-to-settle cows in calf.[118]

When cows have been fed an antibiotic supplement no detectable amount has been found in the milk. On the other hand, when an antibiotic is introduced into a quarter of the udder to treat mastitis, the milk from that quarter should not be used for human consumption for 3 days, because of the presence of the antibiotic.

1051. **Thyroprotein.**—Many experiments have been conducted in this and other countries to determine the effects of adding thyroprotein, or iodinated casein, to the rations of dairy cows.[119] (**54**) These investigations have shown that when thyroprotein is fed under optimum conditions to good cows after they have passed the peak of milk production the milk production is generally increased from 10 to 25 per cent for a period of 4 to 10 weeks. The percentage of fat in the milk is also usually increased slightly. After the feeding of thyroprotein is discontinued, the milk yield is apt to fall below the normal amount, and consequently there may be little increase in milk production for the entire lactation.

The drop in yield can be lessened by gradually withdrawing thyroprotein from the ration, instead of discontinuing it abruptly.

When cows are fed thyroprotein, it is essential that a considerably greater amount of concentrates be fed than normal for the amount of milk produced. Otherwise, they lose much weight and run down badly in condition. To prevent great loss in weight it has been necessary to supply about one-fourth more total digestible nutrients in the ration than normally required. Because of this and also because of the lowered milk yield after thyroprotein feeding is discontinued, appreciably more feed may be required per 100 lbs. milk during the entire lactation when thyroprotein is thus fed.

Feed manufacturers making a formula dairy feed containing thyroprotein add enough of the product so that each pound of the mixed feed contains 5 grams of thyroprotein. They commonly recommend that 3 lbs. of this special feed be given per head daily, in addition to the usual concentrate allowance. Even this extra concentrate supply may not be sufficient to prevent some cows losing much weight, but they regain it when the supplement is discontinued.

It is not advisable to continue feeding thyroprotein during the greater part of the lactation period. In extensive experiments by the United States Department of Agriculture, when cows were fed thyroprotein for 200 to 300 days during successive lactations, the milk and fat production was decreased below normal in later lactations.[120] Also, the death loss of calves was much greater.

For the best results, thyroprotein should not be fed for more than 90 to 120 days, and not during the first 50 days of lactation or in the latter part.

Feeding the drug in hot weather increases the respiration rate so much that the cows may pant and even froth at the mouth. It should therefore not be used during hot summer months. The heart rate is also increased by the drug, but there is apparently no injury to the heart when the recommended amount is fed.

The use of thyroprotein is prohibited by the Purebred Cattle Association of the United States for cows which are on official test. In Great Britain its use in cattle feeds is authorized only for experimental purposes.

After reviewing the experimental data on thyroprotein feeding, the Committee on Animal Nutrition of the National Research Council concludes, "The available data suggest no definite economic advantage of feeding thyroprotein to dairy cows under most farm conditions." [121]

Its use may be advantageous in well-fed commercial herds during periods of short milk supply. Also, in a milk-marketing area where milk is priced on the base-surplus plan, feeding thyroprotein during the base period can raise a dairyman's base quota of milk, and thus increase the price he receives for milk produced during the months of abundant supply.

The limited data available indicate that it is not beneficial to feed thyroprotein to dairy calves.[122]

1052. Preparation of feed.—The various grains should be ground or crushed for dairy cows and heifers, since a considerable percentage otherwise escapes chewing and digestion. The only exception is when grain is unusually cheap, compared with the cost of grinding. Most grain need not be ground for calves up to 6 to 9 months of age.

Medium-fine grinding of grain is decidedly preferable to a floury, dusty meal. It not only takes much less power and time, but also grain ground only medium fine is more palatable and actually has a higher feeding value.[123] (**89**)

Some dairymen prefer a coarse-textured concentrate mixture, or grain mixture, over the usual mixture of ground grains and other concentrates, and will pay a higher price for such a dairy feed. Coarse-textured formula feeds are made by including in them rolled or crimped grain instead of ground grain, pea size oil meals, and sometimes pelleted or crumbled feeds.

New Hampshire and New York experiments have shown that coarse-textured or pelleted dairy feeds have no advantage over the ordinary type of concentrate mixture.[124] In the New Hampshire tests an ordinary fine concentrate mixture was significantly higher in digestible protein and in total digestible nutrients, than a mixture of the same feeds fed in coarse-textured or pelleted form.

Michigan tests show that cows consume their allowance of concentrate mixture more rapidly when water is added to wet it thoroughly.[125] This may be an advantage when cows are fed the concentrate mixture in a milking parlor, and have but little time to eat it.

When cows are fed the usual amounts of concentrates, it does not pay to go to extra expense to chop or grind hay of such quality that it will be cleaned up reasonably well when fed uncut. Such preparation produces little or no increase in the digestibility of the hay. Fine grinding may even lower the digestibility and may cause a decrease in fat content of the milk.[126] (**1030**)

In numerous experiments cows fed chopped or ground hay in ordinary rations have produced no more milk or only slightly more than on uncut hay of good quality.[127] In no case has there been sufficient saving through chopping or grinding such hay to justify the added expense. If cows are fed only alfalfa hay, without any concentrates, it may pay to chop the hay, as they will then eat more hay.[128]

In the case of hay that is unpalatable or coarse and stemmy, there may be enough saving through chopping to warrant the expense, if it can be done cheaply. (**486**) However, it is probably a better plan to feed coarse, stemmy hay liberally, so the cows can pick it over and leave the coarsest stems, which have little feeding value. The refuse can be used for bedding or for feeding stocker cattle or idle horses that are being carried through the winter. Forcing cows to eat the stems of such hay by chopping or grinding does not convert the stems into good roughage. Chopping or shredding corn or sorghum fodder or stover is advisable to lessen the waste, and to facilitate handling the manure.

Where it seems desirable to prepare hay for dairy cows, chopping it by means of a silage cutter or other chopping machine is preferable to grinding it. Ground hay is often disagreeably dusty and may be unpalatable to the cows. Also, it has been found that if cows are fed finely-ground hay as the only roughage, the fat content of the milk may be decreased considerably, especially if they are fed only a small amount of hay.[129] This effect seems to be due to an interference with the normal fermentation processes in the rumen, which are essential for the digestion of roughages.

There is no advantage in mixing the concentrates with chopped or ground hay for dairy cows, although this has sometimes been advocated.[130] Likewise, there is no benefit from soaking or cooking ordinary feeds. In the case of a cow on official test, the concentrate mixture is

sometimes moistened before feeding, in order to induce her to eat a greater quantity than she might take otherwise. Also, dried beet pulp is sometimes soaked and fed as a substitute for corn silage. (943) Fermenting, or "pre-digesting," chopped or ground hay or mixtures of such hay and concentrates does not increase the value and is a waste of time and money. (94)

III. Factors Influencing the Composition and Yield of Milk

1053. Composition of milk.—The milk of the purebred or high-grade cows of any dairy breed has certain general characteristics, particularly in fat content and in color, although the milk of various individuals may differ considerably from the breed average in percentage of fat and total solids. While the fat content of cow's milk may range from less than 3 per cent to 6 per cent or over, there is much less range in the other constituents. The average composition of milk from purebred cows of the different breeds is shown in the following table: [131]

Composition of milk of purebred cows of various breeds

	Total solids	Fat	Protein	Lactose	Mineral matter
	Per cent	Per cent	Per cent	Per cent	Per cent
Ayrshire . . .	13.05	4.05	3.51	4.81	0.68
Brown Swiss	13.13	3.97	3.52	4.90	0.74
Guernsey . .	14.51	4.90	3.90	4.97	0.74
Holstein-Friesian .	12.32	3.45	3.30	4.89	0.68
Jersey	14.86	5.37	3.79	5.00	0.70
Shorthorn . .	12.57	3.63	3.32	4.89	0.73

Jersey and Guernsey milk is the richest in fat, and that of Holsteins the lowest in fat among the common dairy breeds in this country. However, the breeds which give milk high in fat usually yield a correspondingly smaller quantity of milk.

Apparently, the percentage of fat in the milk of purebred Holsteins has been increased appreciably during recent years in the herds of progressive breeders. In 1940 the average fat test of Holstein herds completing records in the Herd Improvement Registry was 3.46 per cent, while in 1954 the average for 2,037 herds and 53,580 cows was 3.67 per cent.[132]

As the fat content of milk increases, the percentage of protein rises less rapidly, and the percentages of calcium and phosphorus increase but slightly.[133] Milk contains about 3.0 per cent or more of casein, the chief protein. Normal milk also has approximately 0.50 per cent of milk albumin, 0.05 per cent of globulin, and traces of other nitrogenous compounds.

The chief difference in the total protein content of milk of various fat percentages is due to a greater or smaller percentage of casein, as the content of albumin and globulin does not differ much. Colostrum, the milk produced the first few days after calving, is very high in globulin, sometimes containing 10 per cent or more. (270)

The casein content of milk is of great importance in cheese making, since the yield of cheese depends not only upon the percentage of fat but also upon the percentage of casein. A milk testing 6 per cent of fat will not make twice as much cheese as one testing 3 per cent. Therefore, at cheese factories where the milk from different herds differs considerably in fat content, it should be paid for by some method which gives credit for both fat and casein.

The hardness of the curd from the milk of various cows differs widely, the curd tending to be harder as the casein content increases. Since soft curd milk is more readily digested than hard curd milk by infants and invalids, special methods are sometimes used to produce soft curd milk for such use. Homogenization makes the curd softer, and other processes have an even more marked effect.

It is well known that the fat in milk is in the form of minute globules or droplets, which are distributed throughout the milk in the form of an emulsion. The fat globules range in size from less than 1 micron to 10 microns or even more in diameter. (A micron is one-

thousandth of a millimeter or about 4 one-hundred-thousandths of an inch.) The minute size of the fat globules is shown by the fact that a quart of normal milk contains 4.5 to 9.0 trillion fat globules.

The fat globules of Jersey and Guernsey milk are larger than those in Holstein and Ayrshire milk, while the globules in Shorthorn milk are of medium size. Regardless of breed, there is a tendency for the fat globules to be larger at the beginning than at the end of lactation.

Practically all the sugar in milk is lactose, but it also contains a trace of glucose.[134]

1054. Factors affecting yield and composition of milk.—In addition to the influence of breed on the composition of milk, the yield and composition are affected by various other factors that have been discussed previously. (305–308) The amount of milk a cow produces is affected much more readily and to a greater degree than is its composition. The chief factors affecting the yearly yield of milk by any cow are her inherited productive ability, her thrift, her age, and the manner in which she is fed and cared for. The daily yield usually reaches a maximum the second month after calving and then decreases gradually as lactation progresses. Such factors as pregnancy, temperature, and turning to pasture may have an appreciable effect on the milk yield.

The fat percentage of milk varies much more than the content of protein, lactose, or minerals. While the average percentage of fat in the milk of an individual cow does not usually change much from year to year, the fat content may vary greatly from one milking to another, and often without any apparent cause. In general, whenever the yield of milk rises or falls considerably, the fat percentage is apt to change in the opposite direction.

The variations in fat content from milking to milking, and from day to day, are much greater than generally realized. In milkings made at the same time on successive days, variations of 0.5 per cent in fat are common and of 1.0 per cent not unusual. The variations in the percentages of fat in successive milkings are often greater than this, as the time of day may have an influence on the fat content of the milk.

Because of the variations in the fat percentage, testing the milk from only one milking is often a poor indication of the richness of the milk a cow is producing. Also, on account of the variations in composition of milk, a dairyman who is retailing milk should be sure to mix the milk from various cows thoroughly before bottling it. Otherwise, some of the milk may fall below the legal standards for fat or solids-not-fat, even though the average composition is satisfactory.

The fat content of milk is affected somewhat by the stage of lactation, tending to increase gradually after the second month. It is also affected by temperature and season of the year, by interval of time between milkings, by age, and by certain other factors. It may sometimes be increased temporarily by adding to the ration certain fat-rich feeds or fats, but the kind of feed does not ordinarily exert any large continued effect upon the fat percentage over a long period of time. Cows calving in fat condition may yield milk abnormally high in fat for some weeks after calving. The character of the fat may be greatly changed by the particular feeds in the ration.

The effects of the ration upon the vitamin content and the mineral content of milk have been discussed in earlier chapters. (307, 308, 1044) From the standpoint of human nutrition an exceedingly important fact is that the vitamin A value of milk depends on the amount of carotene in the ration. Milk from cows fed rations rich in carotene is high in vitamin value, while that produced on carotene-poor rations has a low content. This difference in vitamin A value is also of great importance in raising calves. (1117)

Various factors which affect the yield and composition of milk are discussed in greater detail in the following articles.

1055. Effect of age.—The annual yields of both milk and fat by a cow normally in-

crease from her first lactation until she is mature. This is primarily because of the increase in her size. (1004) The maximum yield is usually reached at 6 to 7 years of age, but the increase is only slight after 5 years.[135] The various dairy breeds differ somewhat in the age at which they reach mature size. Brown Swiss and Milking Shorthorns mature more slowly than Holsteins or Ayshires, and Jerseys and Guernseys mature earliest.

Most cows are removed from the herd because of udder trouble, failure to breed, or other causes before their yield is much reduced by old age. Usually there is no marked decline in yield until 12 years of age, if the cow is in good health.

To compare the production of heifers with that of mature cows, the records are converted to a "mature-equivalent basis" by multiplying the actual yield by an "age-correction factor." Based on extensive studies, Kendrick of the United States Department of Agriculture has prepared tables which state the factors to be used for converting 305-day production records of cows calving at different ages to the mature equivalent basis.[136] For example, the following factors are used for Holsteins: For a heifer calving at 2 years of age, 1.31; for a cow calving at 3 years of age, 1.18; at 4 years, 1.08; and at 5 years, 1.02.

The records of cows calving at older ages than 7 or 8 years are similarly multiplied by factors to convert them to the "mature-equivalent basis."

The fat percentage is affected but little by age, though there is usually a very slight tendency for it to decrease as a cow grows older.[137] In culling cows it is important to bear in mind that while a heifer will ordinarily increase in milk yield with age, the richness of her milk will tend to decrease.

Cows are usually more persistent producers in their first lactation than in later lactations. In other words, the production decreases less rapidly from month to month. This is probably because a heifer is growing in body, and the amount of secreting glandular tissue in her udder is also increasing.

1056. First and last drawn milk; thorough milking.—The milk drawn first from the udder at a milking is usually very poor in fat, and each successive portion increases in richness. While the first portion may have less than 1 per cent fat, the strippings from the same cow may contain 6 to 10 per cent.

There have been several theories concerning the cause of this difference in fat content.[138] The most probable explanation seems to be that the fat globules tend to be retained in the secretory cells of the alveoli, and the other milk constituents pass out first. Then, as the pressure in the udder is released by milking, the fat globules pass out. It was formerly believed that the difference was due to a tendency of the fat to rise in the milk that is contained, previous to milking, in the milk cistern and large ducts of the udder.

If the udder is massaged before milking starts or if the cow has just had considerable exercise, the difference is much less than if she has been standing quietly in the stable. It also tends to be less in low-producing cows than in high producers. Since the strippings are so much richer in fat, the yield of fat and the richness of the milk are appreciably decreased when cows are not milked thoroughly. The percentages of other constituents than fat vary but little in the successive portions of milk drawn from the udder.

Foremilking, or discarding the first few streams of milk from each quarter of the udder, is sometimes done to increase the fat content of market milk. The discarded milk is then used for feeding calves or other stock. However, New York tests show that a considerable part of the milk must be discarded to make any very marked increase in the richness of the remaining milk.[139] Discarding the first 20 streams from each quarter increased the fat content of the rest of the milk only 0.17 per cent. Yet, to obtain this increase nearly 10.5 per cent of the entire milking was discarded.

To secure an accurate index of a cow's production on an official test, it is important that she be milked clean at the milking before the test period starts. Incomplete milking previously will tend to slightly increase the yield of milk, the percentage of fat, and the yield of fat during the test period.[140]

The importance of proper milking and the way in which cows "let down" or "hold up" their milk are discussed in the next chapter. (1093)

1057. Length of period between milkings; night and day.—When the intervals of time between milkings are unequal, cows generally yield a smaller amount of milk after the shorter period, but this milk is usually slightly richer in fat and total solids.[141] With cows milked twice a day, a difference of 4 hours in the two periods may make a difference of 0.5 to 1.0 per cent in fat content.

If cows are milked twice a day with

equal intervals between milkings, the evening milking tends to be slightly richer in fat than the morning milking. This may be due to the effect of the exercise during the day. When cows are milked three or four times a day, the milkings during the middle of the day tend to be slightly higher in fat.

When cows are milked twice a day, it is often desirable because of labor convenience to have a shorter interval between the morning and night milkings than between the night and morning milkings. In a Minnesota experiment with identical twins, the productions of milk and fat were just as high when the cows were milked at 10 and 14 hour intervals as when the intervals were equal.[142]

1058. Frequency of milking.—Milking cows of ordinary productive capacity more than twice a day does not markedly increase their production, and is generally not economical. However, if cows capable of higher production are milked more than twice a day and are fed concentrates according to production, the milk yield will usually be increased considerably.[143] This is because the rate of milk secretion decreases as the pressure within the udder grows greater when it becomes filled with milk. (296) Whether or not it will pay to milk good cows more than twice a day will depend upon the price received for the milk, in comparison with the cost of labor.

Milking cows of high productive capacity more than twice daily tends to increase their persistence in production throughout the lactation and may increase the fat test slightly. The increase in yield by milking 3 or 4 times a day will be greater for heifers than for older cows.

From extensive studies of the available data, Kendrick of the United States Department of Agriculture has estimated that when cows are milked 3 times a day throughout the lactation the average increase in yield over twice-a-day milking, with the more liberal feeding that generally accompanies it, will be about 20.5 per cent for heifers 2 to 3 years old at calving, 17.6 per cent for cows 3 to 4 years old at calving, and 14.9 per cent for those 4 years old or older.[136] The increase in yield over twice-a-day milking from milking 4 times a day will average 35.1, 29.9, and 26.6 per cent for cows calving at these ages.

To convert records of milk production of cows milked 3 or 4 times a day to the basis of twice a day milking, factors are used which depend on the number of days a cow has been milked more than twice a day.[136] For example, if a heifer calving at 2 to 3 years of age has been milked 3 times a day during a 305-day lactation, her actual milk yield is first equated to the mature-equivalent basis and then multiplied by the factor 0.83. If she had been milked 4 times a day during the entire lactation period, the factor 0.74 would be used.

1059. Effect of advancing lactation and of pregnancy.—After calving, the milk yield of cows usually increases until it reaches a maximum during the second month of lactation. It then gradually decreases as lactation advances, the average monthly decrease in well-bred herds being about 6 or 7 per cent from the second to the seventh month.[144] The monthly rate of decrease varies considerably in individual cows, ranging from only 4 per cent or less to 9 per cent or more, depending on their persistency of production. After the seventh month, the rate of decrease is considerably more rapid in cows bred to calve with the usual frequency. Cows of the dual-purpose breeds are usually less persistent milkers than cows of the special dairy breeds, and their monthly rate of decline is more rapid.

Pregnancy does not materially affect the milk yield until after about 5 months, after which it considerably hastens the decline.[145] For this reason, separate classifications are provided in the advanced registries of the dairy breeds for cows which meet definite calving requirements.

In the case of cows which are in good flesh at calving time, the fat percentage is apt to decline slightly for the first month or two after calving. This decrease is most marked in the case of Holsteins and Ayrshires. After the second or third month the fat content usually increases slightly, especially toward the end of lactation. Under usual farm conditions there is no marked change in richness until toward the end of lactation, when the fat percentage increases as the milk yield declines rapidly. In New Zealand studies advance in lactation did not affect the size of the fat globules.[146]

1060. Weather and season of the year.—The temperature of the air has an even more marked effect than the stage of lactation upon the fat percentage in milk.[147] Cows of all breeds tend to give milk lower in fat as the temperature rises, at least between the range from 30° to 70° or 80° F. The fat content may fall as much as 0.2 to 0.3 per cent for each 10° F. increase in temperature. The solids-not-fat percentage of milk also declines as the weather becomes

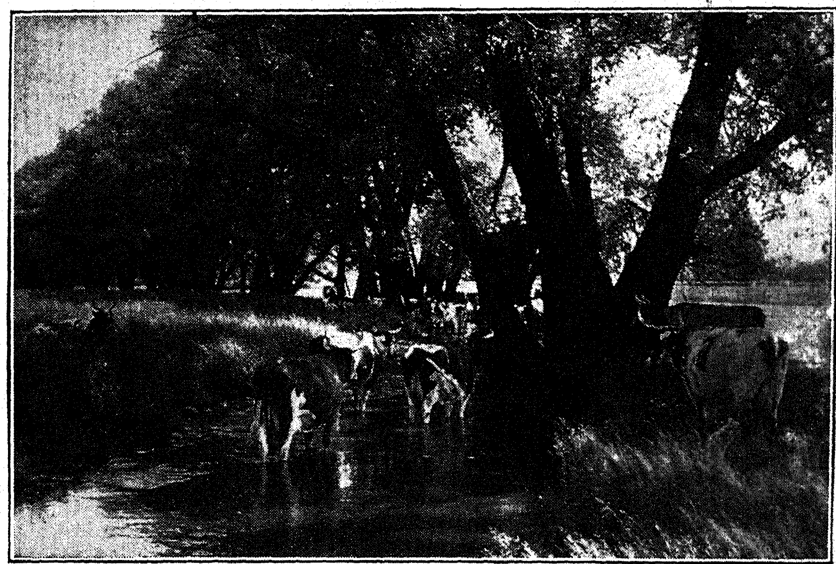
hot, and it may even fall below the common legal standard of 8.5 per cent. Because of the effect of temperature, cows at the same stage of lactation tend to give richer milk in winter than in summer. In hot climates the average fat content and the solids-not-fat tend to be lower than in cooler regions.

Very hot weather has a marked effect upon cattle of our ordinary breeds, as has been pointed out in Chapter VIII. (233) This is because they cannot sweat appreciably and they do not have any efficient means of ridding their bodies of surplus heat. Their body temperatures therefore rise decidedly and their respiration rates become much more rapid, because they pant in an effort to get rid of the surplus heat.

If the weather is extremely hot, it may cause a marked reduction in milk yield, and the fat content may then be increased and the composition of the milk otherwise changed. This effect is most pronounced when the period of hot weather is prolonged. Often the decline in production of cows in hot weather in midsummer is caused to a much greater extent by a shortage of feed on scanty pasture, than by the heat.

In a California test cows kept in a green pasture field in very hot weather were much more comfortable than when confined to a bare corral, and their body temperature was appreciably lowered.[148] This was because the air immediately above the green forage was about 10° F. cooler than in the corral, because of the cooling effect produced by the evaporation of water from the growing plants. This shows the importance of pastures for cows in hot weather.

Shade should be provided on pastures in hot weather, if possible. In a Louisiana test the body temperature of cows kept in the sun in hot weather was 0.7° F. higher than when they were allowed access to shade.[149]



COMFORT OF COWS AFFECTS MILK YIELD

Shade in hot weather and access to a stream or pool in which the cows can wade increase their comfort. (From New York State College of Agriculture, Cornell University.)

Where cows have access to a stream or pool in which they can wade, it increases their comfort in hot weather. Cooling cows during periods of very hot weather by covering them with light muslin cloths kept moist to cause cooling by evaporation, overcame the depressing effect of the heat in a Georgia test, with no bad effect on health.[150]

When the weather is very hot, cows graze more at night than in the daytime. It is therefore important to have them on good pasture at night. Also, the forage on the daytime pasture should be plentiful, so the cows can get their fill before they stop grazing because of the heat.[151]

Exposure to cold rains or other severe

weather may cause a serious shrinkage in milk yield and a drop in fat content.

The effects upon cows of various stable temperatures are discussed further in the next chapter. (1088)

1061. Season of freshening.—Under the climatic conditions in the chief dairy districts of the United States, cows that freshen in fall or early winter, if properly fed and cared for, yield more milk and fat than those that calve in spring or summer. Fall-fresh cows give a large flow of milk in winter and then flush again with the stimulus of pasture in spring. The difference in average annual yield of cows freshening in fall and early winter and of those calving in spring or summer has usually ranged from 11 per cent or more to only 2.5 per cent.[152] In a region with a rather uniformly mild climate, as Western Oregon, the season at which a cow freshens may have no appreciable effect on yearly production.

The relative profitableness of "winter dairying" and "summer dairying" will depend on the prices received for milk at various seasons of the year and the relative cost of concentrates compared with pasture. (1100) When cows freshen in the fall, more of the work of milking comes in the winter when farm work is slack. More time can be given to raising the calves, and fall-dropped calves are large enough by spring to make good use of pasture and are better able to stand the hot weather. Also, under this system, on farms where the milk is separated on the farm, a larger supply of skimmilk is available for pigs or poultry in winter when it has the greatest value for them.

1062. Condition of flesh at calving.—It is well known that the milk yield of a cow is greater when she is in thrifty, vigorous condition at time of calving. The fat content of the milk is not usually affected greatly by the condition of flesh at calving, except in the case of cows which are so fed that they are really fat at calving.

When a cow of high productive capacity calves in a fat condition, her milk for a time may be considerably richer than normal in fat.[153] This is because her strong dairy temperament causes her to withdraw fat from her body and put it into her milk. During this time she will lose markedly in body weight. In the case of Holstein-Friesian cows the increase in fat percentage may be as great as 1 to 2 per cent. Any increase in the case of Guernseys and Jerseys is usually much less marked, and often there is none at all.

It is evident that when a cow calves in fat condition, a short-time record of fat production secured shortly after calving may not be a reliable index to her yearly fat yield. For this reason, brief official advanced registry tests are no longer sponsored by any of the dairy breed associations in this country.

The total yearly yield of fat can be increased by having cows calve in fat condition, and breeders running cows on advanced registry test usually take advantage of this fact.

1063. Influence of underfeeding and overfeeding.—If good dairy cows are underfed in the first part of the lactation period, they will sometimes maintain their milk flow at a nearly constant level for a short time under the most adverse conditions, drawing on their bodies for nutrients and losing in weight rapidly.[154] During this time the percentage of fat in the milk may be temporarily increased, if the cows were in good condition when the underfeeding started.[155] Underfeeding may also produce marked effects on the character of the butterfat. Later in the lactation period, even moderate underfeeding causes a large decline in milk flow, and it is then difficult to bring it back to normal by later liberality of feeding.

When cows are greatly underfed for considerable periods, the percentage of solids-not-fat may be decidedly reduced, and especially the percentage of protein.[156] Scanty feeding within reasonable limits does not apparently have any effect on the flavor of milk.[157] Starvation for a few days greatly decreases the yield of milk and may change its composition considerably.[158]

The most pronounced effect of overfeeding (feeding a more liberal ration than required) is to cause a cow to gain in weight, provided that the overfeeding does not cause her to go off feed.[159] Even when fed very liberally, a cow is unable to increase her milk flow beyond the fixed maximum she has inherited.

1064. Influence of feed on composition of milk.—If a cow receives enough nutrients to maintain her body weight and if her ration contains at least a certain minimum amount of fat, the richness of her milk cannot be increased very markedly over a long time by greater or less liberality of feeding or by supplying any particular kind of feed. Decided changes in the ration may, however, sometimes cause a marked temporary change in the fat content.[160] This effect usually lasts only a few days, and sometimes

there is no increase in the percentage of fat, or even a decrease.

A temporary increase in the fat content of milk is especially apt to result from adding to the ration a considerable amount of certain feeds high in fat, such as flaxseed, soybeans, cottonseed, or peanuts, or from feeding 1 lb. or more per head daily of certain fats or oils, such as butterfat, lard, tallow, coconut oil, linseed oil, cottonseed oil, or corn oil. Linseed meal, cottonseed meal, or soybean oil meal are less apt to produce such an increase, probably because most of the fat has been removed. Feeding a considerable amount of whole milk to cows that will take it also usually increases both the yield of milk and the fat percentage temporarily.

Coconut meal and palm-kernel meal in some tests have apparently caused a very slight increase in fat content for a considerable period, but in other cases the richness of the milk has not been increased.[161] In a New York experiment a trifling increase in the richness of milk was produced by substituting 10 per cent of coconut oil meal and 10 per cent of palm-kernel oil meal for equal amounts of more common feeds in the concentrate mixture.[162] The increase in fat percentage over 5-week periods was only 0.08 per cent, and was thus too small to be of practical importance. It has been previously shown that concentrate mixtures containing 25 per cent or more of soybeans tend to increase the richness of the milk, but they decrease its vitamin A content. (798)

In Ohio experiments in which rations very rich in protein were compared with rations extremely poor in protein, there was no appreciable change in the composition of the milk, except a slight increase in non-protein nitrogen on the ration very high in protein.[163]

Cod-liver oil and also menhaden fish oil cause a decided decrease in the fat content of milk when cows are fed 4 to 5 ounces per head daily.[164] Salmon oil or shark liver oil does not have any marked effect, nor does hydrogenated cod-liver oil.

The principal mineral constituents of milk are not changed to any appreciable extent by the amounts of minerals in the ration. (307)

1065. Changes in the character of fat.—While the feed does not usually change the percentage of fat in the milk much, in some cases the nature of the fat is decidedly altered by the feed, and this may noticeably affect the hardness of butter.[165] Butterfat is made up of several different kinds of fats. Some of these, such as stearin and palmitin, are solid at ordinary temperatures, while others, as olein and butyrin, are liquid. If cows are fed a considerable amount of a feed rich in fat, some of this food fat may pass without great change into the milk, thus altering the fat in a manner similar to the effect on pork when hogs are fattened on certain feeds. (276)

Feeds rich in vegetable oils (which contain a large amount of olein) generally produce butterfat high in olein. This usually tends to make the butter softer, but in some instances this tendency is offset by still other changes in the composition of the fat.

For instance, though the feeding of cottonseed meal, cottonseed, or cottonseed oil increases the amount of olein in the butterfat, yet it raises the melting point and makes the butter harder. This is probably due to a decrease in the amount of volatile fatty acids, which more than counterbalances the effect of the increase in olein. This effect of the heavy feeding of cottonseed meal or cottonseed on butter is of much practical importance in the southern states, for it is a cause of hard, gummy butter. Coconut oil meal or barley increases the hardness of butter, while corn and oats have a slight effect in the other direction.

The feeding of cows exclusively on alfalfa hay may cause sticky or crumbly butter, which condition can be remedied by adding corn silage to the ration, and also by special processes in manufacture.[166] Soybeans and rice polish make the butter soft, if they form too large a part of the concentrate mixture. Pasture generally produces milk fat higher in olein and hence causes softer butter. Jerseys seem to produce harder butter than Holsteins or Ayrshires when fed the same rations.

1066. Miscellaneous factors.—*Moderate exercise* tends to increase slightly the percentage of fat in milk and also the yield of fat.[167] For this reason and also to provide fresh air and sunshine, it is a sound plan in winter to turn cows out for exercise a part of each day when the weather is suitable. Too much exercise, or hard work, such as milk cows are often used for in some countries, lowers the yield and may decrease the fat content.

Turning cows to pasture from winter stabling usually increases both the yield of milk and its richness, but after 2 to 4 weeks the percentage of fat falls to normal.[168] The temporary increase in richness is probably due to the fact that early spring pasture is so watery that the cows do not get enough

nutrients and are therefore forced to draw on their bodies, losing weight meanwhile. Such underfeeding usually increases the richness of milk temporarily, if the cows are in a good state of nutrition when it starts.

Abortion causes a decidedly lower yield of milk than normal, the reduction being especially great if it occurs a considerable time before the time for normal calving. The eradication of brucellosis, or Bang's disease, from a herd greatly increases the milk yield and therefore causes a considerably greater net return.[169]

The *period of heat*, or estrus, contrary to popular opinion, does not generally have any marked effect on the yield of milk or fat. Cows have been found, on the average, to give 0.6 lb. to 1.5 lbs. less milk on the day of the most evident heat, but some cows showed no decrease at all.[170] A few nervous cows are affected more markedly.

Grooming cows is, of course, necessary in the production of high-quality milk with a low bacterial content, but it may not increase the yield of milk.[171] Grooming cows with a vacuum-cleaner type of grooming machine causes little or no increase in yield over hand grooming.[172]

Dehorning cows causes a small temporary decrease in milk flow, but it is repaid a hundred-fold in commercial dairy herds in the greater comfort of the cows thereafter and the lessening of injuries. From the standpoint of dairy efficiency, it is unfortunate that in the case of certain breeds, animals without horns are discriminated against in the show ring.

The *tuberculin testing* of cows has practically no effect on the yield of milk or fat.

Infestation with ticks may cause a serious decrease in yield, even when cows are immune to tick fever.[173] Therefore the eradication of ticks is very important in tick-infested districts.

Condimental stock foods or *tonics* are unnecessary in the efficient feeding of dairy cattle. In two Michigan trials there was no benefit whatsoever from the addition of a widely-used stock tonic to a simple ration of legume hay, corn silage, and a mixture of corn, barley, oats, linseed meal and cottonseed meal.[174] In fact, the feeding of the stock tonic according to the directions of the manufacturers caused some of the cows to go off feed and produced bloating in several cases.

Certain *drugs* have been supposed by some dairymen to increase the yield of milk or fat, and occasionally attempts have been made by unscrupulous persons to increase the yields of cows on official test by the use of drugs. In most of the tests of such products there has been no decided increase in the yield of milk or fat over a 24-hour period.[175] Often, "drugging" a cow has resulted in a marked decrease in yield instead of an increase. The effect of thyroprotein on milk production has been discussed previously. (1051)

1067. Flavor and odor of milk.—Because of the importance of the flavor and odor of milk, numerous studies have been made of the effects of various feeds on the palatability of milk and its products.[176] In the case of most feeds which affect the flavor or odor of milk, the effect, at least in a well-ventilated barn, is produced chiefly by substances carried in the blood to the udder, and not by odors absorbed by the milk from the stable air. Tests have shown that the flavor may be affected not only when a cow eats the feed, but even when she inhales the odor of the feed. An off-flavor caused by feed can usually be prevented or at least greatly lessened by feeding the particular feed only immediately after milking. Since most compounds that produce off-flavors are volatile, they will largely pass off before the next milking.

The most marked off-flavor is produced by garlic, onions, the cruciferae (including turnips, cabbage, rape, and kale), and certain weeds, including bitterweed (*Helenium tenuifolium*) and French weed or stinkweed (*Thlaspi arvense*). Green alfalfa, green sweet clover, and legume silage may also cause a pronounced flavor if fed within 5 hours before milking. Corn silage, green corn, green rye, or potatoes may produce a less marked effect if fed before milking. Even alfalfa hay may cause a noticeable flavor if fed less than 4 hours before milking. When cows are first turned to pasture, a grass flavor is at once noticed in the milk, but this soon disappears, or else we then fail to notice it.

Heating the milk to 145° F. and aerating it or blowing air through it usually removes much of any objectionable feed odor or flavor, and may entirely eliminate slight taints. If a pasture is infested with leeks or wild onions, a pronounced taint may usually be avoided by grazing the cows on the pasture only 2 or 3 hours immediately after milking.

Sometimes, especially late in the lactation period, a cow gives milk which tastes rancid or bitter after standing a short time. This rarely happens when the cow receives green feed. The trouble is caused by an

enzyme in the milk that acts on the fat. It can be prevented by heating the milk, immediately after milking, enough to destroy the enzyme, and then cooling it.

On storage, milk sometimes develops an off-flavor known as oxidized, cardboard, or tallowy flavor, due to changes in unstable constituents of the milk. Homogenized milk has less tendency to develop oxidized flavor, but on exposure to light is much more susceptible to another type of off-flavor. Experiments are being conducted by dairy scientists to find practical methods of treating or handling milk to reduce trouble from these off-flavors. There seems to be less tendency for oxidized flavor to occur when cows are fed some kinds of roughage. In New York tests, less oxidized flavor developed with orchard grass pasture or birdsfoot trefoil hay than with Ladino clover pasture or hay.[177]

QUESTIONS

1. Compare the efficiency of dairy cows and beef steers in the production of human food.
2. What do dairy-herd-improvement-association records show concerning the relative income above feed cost from high-producing cows and from low producers?
3. Why are high producers more efficient than low producers in converting feed into milk?
4. How is the amount of 4 per cent fat-corrected milk computed?
5. What is the approximate gross efficiency of dairy cows yielding about 10,000 lbs. of 4 per cent fat-corrected milk a year?
6. Why does scanty feeding reduce the efficiency of cows of high productive capacity?
7. Describe the results that have been secured in experiments in which purebred bulls have been used to develop a good herd from scrubs.
8. Compare dairy cows and beef-type cows in efficiency of milk production; compare purebred and grade dairy cows.
9. How does size of cow affect milk yield?
10. Discuss the importance of records of production in building up a profitable dairy herd.
11. What are dairy-herd-improvement associations; owner-sampler clubs?
12. Which is the better measure of the productive ability of a dairy herd—official tests of selected cows, or consecutive yearly herd tests of all the cows?
13. State 6 nutrient requirements of dairy cows for efficient production.
14. Why is not the common "thumb rule" as accurate a guide as the grain feeding tables, for determining the amounts of concentrates needed by individual cows?
15. Why must feeding standards recommend slightly greater amounts of nutrients than dairy cows actually require?
16. How much digestible protein and how much total digestible nutrients should be provided for maintaining a 1,000-lb. dairy cow?
17. Discuss the amount of protein required by dairy cows for milk production.
18. Show by an example how the protein content of the concentrate mixture for dairy cows should depend on the protein content of the roughage.
19. About what percentage of protein should a concentrate mixture contain for feeding with good mixed clover-and-timothy hay and corn silage?
20. Discuss quality of protein in dairy rations.
21. Under what conditions should urea be used as a partial protein substitute?
22. Discuss the fat requirements of dairy cows.
23. Why is a range indicated in the amounts of total digestible nutrients recommended in the Morrison feeding standards for milk production?
24. Discuss the replacing of concentrates by high-quality roughage.
25. What are the two points of view concerning the need of a lactation factor for high milk production?
26. Discuss the results of the "input-output" experiments in which increasing amounts of concentrates have been added to the rations of good cows.
27. What factors determine the level of concentrate feeding that will be most profitable?
28. Discuss the feeding of good dairy cows on roughage alone.
29. Tell about the Indiana demonstration which showed that it pays to feed good cows liberally.
30. Under what conditions may it be economical to restrict the amount of roughage fed dairy cows?
31. What is the relative value per pound of good hay and of a good concentrate mixture for milk production?

32. What is the effect of feeding cows only 2 to 4 lbs. of hay and no other roughage?
33. What is the effect of including ground alfalfa hay in a dairy concentrate mixture?
34. What are the salt requirements of dairy cows?
35. Under what specific conditions should a phosphorus supplement be added to the rations of dairy cows?
36. When would you add a calcium supplement to dairy rations?
37. Discuss the losses and storage of calcium and phosphorus by dairy cows.
38. What results have been secured when calcium and phosphorus supplements have been added to good dairy rations?
39. Discuss trace mineral supplements for dairy cows.
40. Discuss the vitamin requirements of dairy cows.
41. When may deficiencies of vitamin A occur?
42. Discuss the effect on the vitamin A value of milk and butter of: (a) Breed of cow; (b) the ration fed.
43. What is the effect of adding a vitamin supplement to a good dairy ration?
44. What have experiments shown concerning any need of adding a vitamin D supplement to ordinary dairy rations?
45. Discuss the use of mineral or vitamin supplements to prevent breeding troubles.
46. Discuss the water requirements of dairy cows, considering: (a) Amount required; (b) use of drinking bowls.
47. Is it beneficial to add an antibiotic feed supplement to rations for dairy cows?
48. Discuss the use of thyroprotein in dairy rations.
49. Discuss the grinding of grain for dairy cows; the chopping or grinding of hay.
50. About how much fat, protein, lactose, and mineral matter does cow's milk contain?
51. What are some of the factors which affect the yield and composition of milk?
52. Discuss the effect upon yield and composition of milk of any of the factors considered in Articles 1055 to 1067 which are assigned by your instructor.

CHAPTER XXVI

FEEDING AND CARING FOR DAIRY COWS

I. Feeding for Milk Production

1068. Essentials in feeding and care.—The net return a dairyman receives from his dairy business depends equally on the productive capacity of his cows and on the feed and care he gives them. Just as necessary as well-bred cows, capable of high yields, are efficient rations and intelligent care. Without these, good cows are forced to become poor and unprofitable producers.

The chief essentials in the proper feeding and care of dairy cows are:

1. The use throughout the year of economical, well-balanced rations, which provide the nutritive requirements that have been discussed in the previous chapter.
2. Adjusting the amount of concentrates for each cow to her actual production.
3. Palatable rations, containing a reasonable variety of feeds.
4. Rations that are slightly laxative, instead of constipating.
5. An abundance of good roughage, and some succulent feed, except when succulent feeds are unduly expensive.
6. Plenty of good water, conveniently accessible.
7. Dry periods of proper length.
8. Comfortable surroundings, both in winter and during the pasture season.
9. Regularity in feed and care.
10. Kindness on the part of the herdsman.

Neglect of these simple essentials will seriously reduce the net income from the dairy herd.

Commonly, dairy cows are fed roughage—hay or hay and silage—twice a day and concentrate or grain mixture at or before milking.

1069. Cows should be fed individually.—To secure good net returns from a dairy herd, it is necessary to feed each cow according to her actual yield of milk and fat. A high-producing cow needs a much greater amount of total digestible nutrients than a low producer. Since she cannot eat much more hay or other roughage than a low producer, she must be fed a liberal amount of grain or other concentrates. Otherwise, her milk yield will soon fall to the level that is permitted by the amount of nutrients she actually receives.

In spite of the great difference in the real needs of the various cows in a herd, many dairymen make the mistake of feeding all their cows the same amount of concentrate or grain mixture, regardless of their actual yields. This practice seriously underfeeds the high producers and therefore reduces the net returns from the herd. It just as seriously overfeeds the poor cows. They are unable to convert the excess nutrients into milk, but instead turn them into body fat or waste them entirely.

The amount of grain mixture needed by a cow depends not only on her yield of milk and fat but also on the amount and quality of the roughage she eats. The simplest way of finding the number of pounds of grain mixture that should be fed to each cow per day is to use the grain feeding tables given in Appendix Table VIII. These tables, which have been discussed in the previous chapter, show at a glance the amounts of grain mixture needed by cows producing various amounts of milk of any fat content when they are fed different amounts of roughage, or when on excellent, good, or fair pasture.

It has been emphasized in the previous chapter that the most profitable level of concentrate feeding will depend on the local conditions, especially on the relative cost of concentrates and rough-

ages, on the price of milk, and on the quality and abundance of roughage. (**1022–1028**) As there pointed out, under certain conditions the greatest net return may be secured, even from good cows, when they are fed an abundance of high-quality roughage with little or no concentrates. On the other hand, when milk is high in price in comparison with the cost of concentrates, it may be most profitable to feed larger allowances of concentrates, or grain mixture, than stated in the grain feeding tables.

GOOD COWS NEED BETTER ROUGHAGE

A limited amount of dry corn stover or corn fodder can be fed satisfactorily to dairy cows, along with better roughages, such as legume hay and silage. However, corn stover or corn fodder is not efficient as the only roughage.

As pointed out in the preceding chapter, self-feeding dairy cows is ordinarily not desirable. (**1032**)

1070. Palatable rations.—Both the roughages and the concentrate mixture for cows producing a good yield of milk should be as palatable as possible. If the roughage is not palatable, the cows will eat much less of it than they would of well-liked roughage, and it will be necessary to feed them an unusually large amount of concentrates.

Such roughages as corn stover, grass hay cut at the usual stage of maturity, and even straw can be fed to dairy cows in limited amounts, along with better roughage. However, for the best results they should not form the chief roughage for good cows. It is preferable to feed two kinds of roughage to dairy cows, for when fed even good alfalfa hay continually as the only roughage, they show a keen desire for other roughage in addition, and seem to thrive better when receiving it.

It is usually easy to provide a palatable concentrate mixture, or "grain mixture," for dairy cows, for they like most all the common grains and byproduct concentrates, if the feeds are of ordinary quality. Sometimes it is economical to include in the grain mixture a feed like malt sprouts or rye feed, which is not itself palatable. This may be done without making the whole mixture unpalatable, if only a reasonable amount is mixed with well-liked feeds, such as ground corn, ground oats, wheat bran, linseed meal, molasses, etc.

1071. Variety.—There is considerable difference of opinion concerning the

need of "variety," or of several different ingredients in a concentrate mixture for dairy cows.

When cows of ordinary productive capacity have good roughage, including a reasonable amount of legume hay, it is not necessary to go to extra expense to use a concentrate mixture which has several ingredients. For example, it has been shown in the previous chapter that if cows have plenty of alfalfa hay and corn silage for roughage, or if they are fed alfalfa hay as the only roughage, good production can be secured when they receive in addition such a simple grain mixture as one-half ground corn and one-half ground oats. (**1016**)

The palatability and nutritive merits of the individual feeds in a concentrate mixture are of greater importance than the number of ingredients. A concentrate mixture containing a reasonable variety of well-liked ingredients is, however, apt to be more palatable than a simple combination, such as a mixture of grains, or of grains and a single protein supplement. Many dairy experts therefore advise that for high-producing cows, especially those on official test, the concentrate mixture should contain 5 or 6 ingredients.

Several experiments have been conducted to compare such a simple concentrate mixture as ground corn or corn and oats, supplemented by soybean oil meal or cottonseed meal, with a mixture having much greater variety and usually having more bulk.[1] When the protein content of the mixtures has been equal, there has been no appreciable difference in the yield of milk or fat, or in the effect on the live weights of the cows. These experiments have been conducted with cows fed good roughage, such as well-cured hay and silage, or with cows on pasture. It is barely possible that with poor-quality roughage there might be an advantage from a concentrate mixture containing a greater variety of feeds.

It has previously been shown that the kind or quality of protein in rations for dairy cows is of little importance when the rations contain good roughage and are made up of feeds that are otherwise satisfactory. (**1018**) In New York experiments there was also no difference in the results from a concentrate mixture made up largely of home-grown grains and one made up chiefly of by-product feeds.[2]

If a satisfactory ration is being fed, there is no advantage in changing it from time to time, in order to supply additional variety. While humans would tire of a monotonous diet, stock fortunately do not have such fickle appetites.

If cows accustomed to a good grain mixture are changed to another equally good, but having a decidedly different taste, they may at first not like the new mixture. However, in nearly all cases they will soon become used to it. When cows which have been on advanced registry test and have had their whims for special feeds indulged by expert herdsmen are returned to the regular herd, it often takes them some time to become accustomed to the less-luxurious manner of life.

1072. Bulkiness of concentrate mixture.—It is a common belief that when high-producing cows are fed a liberal amount of concentrates, there will be less tendency for them to go off feed if some bulky feeds, such as wheat bran, ground oats, or dried beet pulp, are included in the mixture. Many experienced dairymen prefer a concentrate or grain mixture which does not weigh more than about 1 lb. to a quart.

For cows fed the usual amount of grain mixture, if it is cheapest to feed a heavy mixture that contains no bulky feeds, the mixture may readily be distributed over silage after the latter has been placed in the mangers. This will insure adequate mixing of the concentrates and silage in the digestive tract. On the other hand, it is wise to use only a bulky concentrate mixture for cows that are fed very liberal amounts of concentrates, such as cows on advanced registry test.

In the previous discussion on "variety" it has been shown that with good roughage just as satisfactory results have been secured from such a mixture as ground corn and soybean oil meal or

cottonseed meal, as from a mixture having much more variety and containing bulky concentrates.

In Illinois and Michigan tests heavy concentrates, such as ground corn and linseed meal, were fed to cows separately from the roughage, and the cows were slaughtered soon afterwards.[3] It was found that most of the concentrate was well-mixed with the previous contents of the rumen and the honeycomb, and only a small part was in the form of separate lumps or boluses. In the Michigan experiments a concentrate mixture of only ground corn and linseed meal was satisfactory for feeding dairy cows, even when it was fed separately from the roughage.

Though many dairymen prefer a concentrate mixture that has a coarse texture, experiments have shown no advantage for such a mixture over an ordinary ground mixture made of the same feeds. (**1052**)

1073. Rations that are slightly laxative.—In order to secure the most efficient production, dairy cows should receive rations that are slightly laxative. This is readily accomplished when plenty of well-cured legume hay or good silage is fed. If all the roughage is of a rather constipating nature, such as ordinary grass hay, corn stover, or straw, care should be taken to include in the grain mixture a sufficient amount of laxative feeds, such as wheat bran, linseed meal, or molasses, to counteract the constipating effect of the roughage.

1074. An abundance of good roughage.—The importance of an abundance of good roughage has been fully discussed in the preceding chapter. (**1022–1029**) The results from supplying plenty of high-quality roughage are well shown by a recent cost study on Michigan farms.[4] On the farms where abundant excellent roughage was provided, the average milk yield per cow was 12,043 lbs., and 2,614 lbs. of grain and only 189 lbs. of protein supplements were fed. Where the roughage supply was poor, good production was also secured (an average of 11,727 lbs.), but it was obtained by feeding much more grain and protein supplements (3,921 lbs. grain and 519 lbs. protein supplements). With the excellent roughage supply, the feed cost per 100 lbs. milk was 46 cents less and the net return per cow $65 more than with poor roughage.

In most of our dairy districts it is economy to supply dairy cows with an abundance of good hay during the barn-feeding season. The only usual exception is where the weather is such that it is very difficult to make satisfactory hay. Under these conditions cows should be filled up with good silage, but a small amount of hay should be fed in addition, if possible.

If cows are fed all the well-cured hay and other good roughage that they will eat, considerably less concentrates are needed to keep up a high milk yield than when the supply of roughage is scanty or of poor quality. (**1022**) If one has plenty of hay, it is an excellent plan to feed it so liberally to good cows that they leave some of the coarser stems. These less nutritious parts can be used for bedding or fed to idle work stock. When fresh hay is put before cows more often than twice a day, the amount they will eat is generally increased somewhat.

The values of the various kinds of hay have been discussed in detail in the chapters of Part II. Where possible, legume hay or mixed legume-and-grass hay should be fed to dairy cows, as it is much richer in protein, calcium, and vitamins than the usual quality of grass hay. However, timothy or other grass hay is satisfactory for cows, if it is grown on well-fertilized land, and if it is cut early and well-cured. (**564**) When but little legume forage is fed, the concentrate mixture must, of course, be considerably richer in protein than is needed with an abundance of legumes in the ration. (**1016**)

1075. Succulent feeds.—Succulent feeds, such as silage, are highly desirable for dairy cows, because of the advantages that have been discussed in previous chapters. (**421, 523**) Such feeds are so palatable that when they are included in the ration cows eat more total roughage, and therefore need less concentrates than

when given only dry roughage. Also, because of the cooling and slightly laxative effect, silage and other succulent feeds aid in keeping high-producing cows thrifty. There is especial need of succulent feeds when there is little or no legume hay in the ration.

In this country silage is the common succulent feed for winter feeding. Though roots are an excellent feed for dairy cows, they are so much less economical than silage under our conditions that but few roots are grown for stock feeding. (**627**, **630**) Detailed information on the value of the various kinds of silage for dairy cattle has been given in earlier chapters. In our chief dairy districts corn is the most important silage crop, and in the plains states silage from the sorghums is of similar importance. Silage from alfalfa and other hay crops is excellent for dairy cattle when properly preserved. Such hay-crop silage is even higher than corn silage in carotene, and helps maintain a high vitamin A value in the milk throughout the winter. (**438**)

While silage is highly desirable for dairy cows during the winter, it is not absolutely necessary for good production. If cows are fed a liberal amount of excellent legume or mixed hay and are supplied with water in drinking cups, they may produce nearly as much milk as when they are fed silage in addition. However, unless the dry roughage is excellent, their production will be decidedly greater if they receive succulent feeds. (**503–504**)

Whether or not to supply silage is primarily a question of farm economics and farm management. (**424**) For example, in the corn belt the use of corn silage is generally advisable, on account of its high value and its economy. On the other hand, in certain of the western alfalfa districts nutrients can be provided so much more cheaply in alfalfa hay than in any form of silage that it may not be profitable to use silage.

1076. Amount of silage for dairy cows.—The amount of silage fed per head daily to dairy cows usually ranges from 20 to 40 lbs. per 1,000 lbs. live weight. When cows are fed twice a day all the silage and good legume hay that they will eat, they take about 3 lbs. of silage and 1 lb. of hay daily per 100 lbs. live weight, in addition to the usual amount of concentrate mixture. If the hay is of excellent quality, they may eat a little more hay than this.

Most dairymen who have plenty of both silage and hay let their cows have all of each that they will clean up, except perhaps in the case of cows on official test. Limiting the amount of silage and hay for such cows may induce them to eat more of the concentrate mixture.

Practically all of the advantage from feeding silage to cows can be gained when no more than 15 to 20 lbs. per head daily is fed, along with a very liberal amount of hay.[5] Where the cost of nutrients in silage is relatively high compared with the cost in hay, it may therefore be most economical to give the cows all the hay they will take and only half the usual amount of silage. If the hay is of especially good quality, they may consume even more dry matter and total digestible nutrients in roughage when thus fed than if given more silage. They will then need less concentrates to keep up a good yield of milk.

On the other hand, in sections where the weather makes the curing of hay difficult, it may be desirable to use silage as the only roughage, or to feed only a small amount of hay with all the silage the cows will eat. It should be borne in mind, however, that ordinarily the easiest way to provide ample amounts of vitamin D in winter rations is through feeding well-cured legume or mixed hay. (**1046**)

If corn or sorghum silage is fed as the only roughage or with but little hay, it is important to see that the concentrate mixture has plenty of protein to balance the low-protein silage. Also, it is wise to feed a calcium supplement to make sure there is plenty of this mineral nutrient. Cows fed silage as the only roughage will often eat 6 lbs. or more of silage daily per 100 lbs. live weight.

In some experiments the results have been very satisfactory when corn

or other silage has been fed as the only roughage, except for straw the cows may have picked up from the bedding.[6] For example, in an Iowa experiment heifers were paired at birth, and one heifer in each pair was fed corn silage as the only roughage for consecutive years.[7] The other heifer in each pair had hay for the first 6 months and then both hay and silage. All were on pasture in summer after a year of age. The calves having silage as the only roughage did not grow quite so rapidly at first, but by a year of age there was no appreciable difference in size. In 2 lactations the silage-fed cows produced even more milk and fat than those receiving both hay and silage.

Differing from these results, in other experiments it has been necessary to feed a greater amount of concentrates than usual to keep up the milk yield when corn silage or hay-crop silage was the only roughage; or else the milk production has been lowered.[8] Considering all the information available, it seems wise under usual conditions to feed at least 6 or 7 lbs. per head daily of good hay in addition to silage, instead of using silage as the only roughage.

II. Feeding Cows on Pasture

1077. Good pasture necessary for cheap milk production.—No factor is of greater importance in reducing the cost of milk production than providing excellent pasture for the herd over just as long a period as possible. First-class pasture is highly palatable and also very nutritious. As a result, when cows can eat their fill of it, they will get from the pasture forage a decidedly larger proportion of the nutrients they need for high milk production, than when barn-fed on good hay and silage. Good pasture is high in digestible nutrients on the dry basis, and it is also rich in protein, minerals, and vitamins. (358–362)

Unfortunately, in most sections permanent pastures furnish ideal pasturage for only a short season, and in midsummer they are too often parched and brown. The importance of pasture fertilization and the methods by which good pasture can be provided throughout the entire season are discussed in detail in Chapter XIII.

The great economy of providing good pasture for dairy cows has previously been emphasized in Chapter XIII. (357) When well-fertilized and properly-managed pastures are provided, a high yield of milk can be maintained throughout the summer with a minimum amount of grain or other harvested feed. On the other hand, when little effort is made to improve the pastures, a large amount of additional feed must be supplied in order to keep up a good milk flow and to prevent the cows from running down in flesh.

Pasture the Cheapest Feed

An abundance of good pasture is necessary for economical milk production, because such pasture supplies the cheapest feed. (From New York State College of Agriculture, Cornell University.)

The proper feeding of milk cows on pasture is much simpler than is winter feeding, and doubtless this is why so many farmers, busy with their crops, fail to give their herd the necessary attention in summer. Often the cows are merely turned to pasture after milking at night and in the morning, with no further thought as to the supply of feed actually available. It is then no wonder that when the pasturage becomes scanty in midsummer, the cows run down in flesh and fall off severely in yield of milk.

A shortage of feed in midsummer is much more serious for dairy cows than for beef cattle being fattened on pasture. When the pasture becomes scanty, the beef cattle may not much more than maintain their weights, but when the

pasture springs up again after the fall rains, they will make good gains. On the other hand, if the milk yield of high-producing cows is seriously reduced by scanty feed, it is difficult or impossible to bring them back to their former yield by liberal feeding in the fall. Also, succulent, palatable pasturage is more important for dairy cows than for beef cattle.

Care should be taken to provide good pasture for cows at night. In Virginia studies it was found that cows did half of their grazing at night.[9]

In the spring many dairymen make the mistake of turning the herd to pasture before the grass is well started. This not only injures the pasture but also is apt to decrease the yield of milk, for the cows cannot get much nourishment from the scanty forage. It is important, however, that grazing start as soon as the grass is ready. Otherwise, the cattle may be unable to keep the forage grazed down during the period of most rapid growth, and it will then become too mature and will be unpalatable.

When cows in milk are first turned on pasture in the spring, the feeding of some concentrates and also hay should be continued until they become used to pasture and until the grass becomes abundant. If this is not done, good cows will run down in condition. The young grass stimulates them to produce more milk than on their winter ration, but it is frequently so low in dry matter and nutrients that the cows are unable to eat enough of it to meet their needs.

Often cows are left on pasture, without other roughage, entirely too late in the fall. They should be housed in the barn and be on full winter rations before poor pasture or unfavorable weather cuts down their yield. Much of the drop in milk yield that often occurs in the fall can be prevented if the cows are changed gradually from pasture to barn-feeding conditions. During this change plenty of good hay should be fed and also silage, if available. By starting the feeding immediately after silo filling, top spoilage may be entirely avoided.

1078. Pastures for dairy cows.—The value of the various pasture crops is discussed in detail in Chapters XVI and XVIII. Throughout the northern states, bluegrass and combinations of bluegrass with white clover and other legumes are the most common permanent pastures. In the central states and southward, combinations of grasses and lespedeza provide excellent pasture throughout the growing season. In the South, Bermuda grass and other southern grasses take the place of the bluegrass of the North.

Pasture mixtures grown in the regular crop rotation, such as a mixture of alfalfa and brome grass or orchard grass or a combination of Ladino clover and grass, provide a much greater yield than permanent bluegrass pasture. Still more important is the fact that they furnish good feed in midsummer, when bluegrass is often parched and brown.

In the South good pasture can be provided during most of the winter by winter cereal pasture or else winter legumes or legume-and-cereal combinations. Such pasturage will increase the winter milk yield and make a decided decrease in the cost of production.[10] Even in the northern states winter grain provides excellent late fall and early spring pasture.

The carrying capacity of pastures varies widely, depending on the soil and climate and especially on how wisely the pasture is managed. If no supplemental feed is provided for periods of drouth, 1.5 to 2.5 acres of fairly good pasture should be provided per cow, but if such additional feed is furnished and the pasture is properly fertilized, the pasture allowance can be reduced to 1 acre per cow or even less. In the West, irrigated pasture which is well fertilized may carry more than 2 cows per acre throughout the season.

Cows on abundant pasture will eat 90 to 150 lbs. of forage a day, and sometimes 200 lbs. or more. To harvest this amount of grass with her mouth, a cow must graze several hours a day, even when the pasture is good. When the forage is scanty, she spends much more energy in grazing in an effort to get enough feed. In Kansas tests, cows spent 7.3 hours a day grazing on poor pasture,

while they needed to graze only 5.6 hours on good pasture.[11]

1079. Supplementing scanty pasture.—The various methods of supplementing permanent pasture in midsummer are discussed in Chapter XIII. Often the best way is to use for pasture at this season the second crop on a mixed legume-and-grass hay field which has been cut early. Another method is to grow Sudan grass or some other annual pasture crop for summer pasture.

If plenty of forage cannot be provided throughout the summer by one of these means, the cows should be fed silage, hay, or green soiling crops to make up the lack. This is generally much more economical than to try to keep up the production by merely increasing the amount of concentrates. When there are enough cows in the herd to use up silage fast enough to keep it from spoiling, silage is generally a much more economical summer feed than soiling crops. (386)

If soiling crops are used, it should be borne in mind that they are more watery than good corn silage, and hence it is necessary to feed a considerably greater weight.

1080. Feeding cows on pasture.—It is often difficult to decide how much grain mixture to feed cows on good pasture, or whether to feed no grain at all. The answer depends on the amount and quality of the forage the pasture furnishes and on the actual production of the cows.

Good pasture alone will provide cows with sufficient nutrients for body maintenance and the production of about 10 to 20 lbs. of milk, depending on its richness. If the pasture is excellent, it will provide for still more milk. Cows of high productive capacity that are fed no grain mixture on pasture may continue to yield more milk than these amounts, but they must draw on their bodies for the additional nutrients needed. Consequently, they will lose weight and run down in condition.

The "Grain feeding table for cows on pasture" in Appendix Table VIII provides a convenient guide for the feeding of grain or other concentrates to cows on various grades of pasture. Separate recommendations are made for cows on excellent, good, and fair pasture, and for specific yields of milk containing various percentages of fat. These recommendations are based upon the results of the various studies that have been made of the feed requirements of cows on pasture.[12]

Good cows should be fed about the amounts of grain mixtures shown in this table, except when milk is unusually low in price compared with the price of grain and other concentrates. It may then be most economical to feed no grain to cows on good pasture unless they are producing more than 1 lb. of butterfat a day, and to feed higher producers only one-half to two-thirds as much as stated in the table.

Even when the feeding of a grain mixture to cows on good pasture does not result in enough higher production during the summer to show an immediate profit, it may nevertheless be advisable. This is because it will prevent good cows from running down in condition on pasture and will result in higher yields during the following fall and winter.

If cows have an abundance of good forage on pasture, the feeding of hay in addition does not usually increase milk production enough to be profitable.[13] However, on such legume pasture as alfalfa or Ladino clover, providing hay in a rack on pasture may help prevent bloat. (49)

Since young grass and other forage plants are very rich in protein, on the dry basis, there is no need of using a grain mixture that is rich in protein for cows on good pasture. (359) Merely a mixture of farm grains or a concentrate mixture containing 12 per cent protein will provide plenty of protein for cows on excellent pasture, except in the case of unusually heavy producers. This is shown clearly by the results of Michigan and Ohio experiments.[14] In these tests cows on good pasture produced as much or nearly as much milk when fed a concentrate mixture having only 11 to 12 per cent total protein or only a mixture of

grain as others fed a mixture containing much more protein. In no case was the yield on the high-protein mixture enough greater to pay for the additional cost.

Unless the grass is kept growing actively by liberal fertilization and proper pasture management, it will be considerably lower in protein, on the dry basis, during midsummer. It will then be necessary to increase the protein content of the concentrate mixture. Unless the pasture is decidedly poor, however, it will not be necessary to have more than 16 to 18 per cent protein in the mixture.

Various concentrate mixtures suitable for feeding on excellent, good, fair, and poor pasture are given in Appendix Table VII.

III. Feed and Care Before and After Calving

1081. Dry period important.—Dairy cows should have a dry period for a time before calving, as they will then produce considerably more milk in a year than if they are milked continuously.[15]

The rest period enables the cow to rebuild in her body the store of nutrients which she has drawn upon during the height of milk production. Also, a dry period is necessary for proper recuperation and development of the secreting tissues of the mammary gland before another lactation starts. (298) It has been shown in the previous chapter that only during the dry period and the last weeks of lactation can a high-producing cow regain the calcium and phosphorus drawn from her body stores earlier in lactation. (1038) For this reason alone, it is undoubtedly important that good cows have a dry period of reasonable length.

The length of dry period needed depends on the productive level of the cow and on her state of flesh at the end of lactation. High producers should have a longer rest than lower yielders, and cows thin in flesh should be dry long enough and be fed so that they will be in good condition by calving time.

Dairy scientists differ in the length of dry period advised. Some recommend that a good cow should be dry 8 weeks, while others advise a dry period of 30 to 60 days, depending on how much milk the cow has produced and her state of flesh.

From a study of records of cows in dairy herd-improvement associations in 12 states, Klein and Woodward of the United States Department of Agriculture concluded that a dry period of about 8 weeks gave the best annual yield for cows producing 10,000 lbs. of 4 per cent milk a year and calving at 12-month intervals.[16] Either a longer or a shorter dry period reduced the annual milk yield.

Various methods are used in drying off persistent producers. Probably the best and most rapid method is to discontinue milking abruptly, if the cow is not giving more than about 20 lbs. of milk a day.[17] If a cow is giving more milk than this, her production can usually be reduced to this level by severely restricting her feed.

After the last milking, it is best to wash and dry the teats carefully and then to seal the ends with collodion to prevent the entrance of bacteria. If the udder fills so much with milk that there is danger of its becoming congested, the cow should be milked out clean, and only milked again as it may be necessary. This method dries off a cow much more rapidly than the older method of gradually decreasing the frequency of milking, first to once a day, then once in 2 days, etc. This method should not, however, be used for cows having mastitis.

1082. Feed and care during dry period.—Proper feeding during the dry period is important to get the cow into condition for heavy production and also to prevent trouble at calving time. During the barn-feeding season no better ration can be provided than legume hay and silage, with enough grain mixture to get the cow into proper condition before she freshens. Plenty of well-cured hay is important, because it furnishes vitamin D. This is necessary for the rebuilding of the stores of calcium and phosphorus in the bones, which may have been lost during the flush of milk production.

When dry cows are fed legume hay as the only roughage, a mixture of farm grains alone, such as one-half ground

corn or barley (by weight) and one-half ground oats, will provide sufficient protein. It has been the belief of some that the feeding of a concentrate mixture consisting largely of corn to a cow during the dry period would increase the congestion in the udder at calving time. However, in a Kansas test the feeding of corn as the only concentrate during the dry period did not produce any significant difference in the results.[18]

If at least one-third of the roughage, on the dry basis, is legume forage, the grain mixture need not have more than 12 per cent protein. However, if the cows must be fed only low-protein roughage, the grain mixture should have at least 16 per cent protein. Unless the grain mixture contains 20 per cent or more of feeds high in phosphorus, such as wheat bran, linseed meal, or cottonseed meal, 1 lb. of bone meal or other safe phosphorus supplement should be added to each 100 lbs.

Formulas for several grain mixtures that are suitable for feeding with various kinds of roughage are given in Appendix Table VII. A popular mixture for dry cows that are fed little or no legume roughage is 100 lbs. of ground corn, hominy feed, or ground barley; 100 lbs. of ground oats; 100 lbs. of wheat bran; and 50 to 100 lbs. of linseed meal.

If a cow is in fairly good condition when she is dried off, 2 to 4 lbs. of grain mixture a day with good roughage should be sufficient. On the other hand, if she is thin, the amount should be increased to 5 or 6 lbs., or even more. Cows that are to be on advanced registry test are usually fed with great liberality when dry, so they will be fat at time of freshening. (**1103**)

During the pasture season, no additional feed need be furnished dry cows if there is plenty of forage. However, if pastures become scanty, enough additional feed should be fed to get them in the desired condition.

The benefit from getting cows into proper condition by calving time is shown by a New York trial.[19] Good cows which were fed well in the dry period produced an average of 705 lbs. more milk and 23 lbs. more fat than they had yielded in the previous lactation when they had been fed less liberally during the dry period. The previous year they had averaged 112 lbs. lighter in live weight at calving time. The increase in yield was secured by feeding only about 440 lbs. more concentrates during the dry period and during lactation. For each additional 100 lbs. of milk, only 62 lbs. of concentrates were fed, with no additional roughage. Except when milk is very cheap in comparison with the price of concentrates, this would make it decidedly profitable to feed sufficient concentrates during the dry period to get such cows into fairly good condition before calving.

Experiments by the United States Department of Agriculture show that except when cows are to be on official test, or when the price of milk is high compared with the price of concentrates, it does not pay to feed them so liberally during the dry period that they become very fat.[20]

In England the liberal feeding of cows during the dry period is called "steaming them up." Hammond of Cambridge University believes that good feeding for 6 weeks or so before calving is necessary to secure full development of the secreting cells of the mammary gland.[21]

However, it appears that the important point is to have the cows in good condition by calving time, regardless of the method of feeding used. In an Illinois trial cows and heifers fed only ample good roughage before calving produced about as much milk as others "steamed up" by feeding increasing amounts (up to 12 lbs. a day) of concentrate mixture during 6 weeks previous to calving.[22]

In the Tennessee Station herd excellent results have been secured by feeding the cows during the latter months of lactation enough concentrate mixture to get them into good condition by the time they are dried off.[23] During the dry period they are fed only plenty of good roughage. About the same total amount of concentrates is fed in a year as in the usual method. It is reported that with

this method there are fewer difficulties at calving time and less inflammation of the udder. This method is advisable only where cows can be fed abundant roughage of first-class quality.

It is often recommended that for a week or so before calving, a grain mixture should be fed which is very bulky and laxative, such as: (1) Equal parts by weight of ground oats and wheat bran; or (2) equal parts by weight of ground oats, wheat bran, and linseed meal. There is, however, no need of feeding a special mixture, if the ration previously fed has been laxative enough to prevent constipation. The recommendation is also often made that the allowance of concentrates be reduced at this time to only 3 or 4 lbs. a day, if more has been fed. Unless the cow's udder shows a tendency to become congested, it is not, however, necessary to reduce the allowance.

A cow that is soon to calve should be turned out for exercise each day when the weather is suitable. She must not be chased by dogs or be crowded through narrow doors or gates. Care should also be taken that she is not injured by slipping on the stable floor or on ice.

1083. Gestation period; frequency of calving.—In a study of the gestation periods of dairy cows of the various breeds, the United States Department of Agriculture found the average lengths in days for normal calving to be: Holsteins, 278.9; Jerseys, 279.3; Ayrshires, 278.7; Guernseys, 284.0; and Brown Swiss, 290.0.[24] Male calves are usually carried a trifle longer than heifers, and twins a shorter time than single calves. First gestation periods are commonly 1 to 2 days shorter than the average for all ages.

Unless dairymen wish to change the period of freshening in their herds, they usually prefer to have the cows calve at intervals of about 12 months, as this results in the highest annual yield per cow over a period of years. However, the average interval will generally be considerably longer than this, because of difficulty in getting some cows in calf. A much shorter interval than a year is apt to reduce the annual yield, especially in the case of high-producing cows.

When a cow is to be run on advanced registry test the next year, sometimes breeding is delayed a few weeks, as this tends to cause a higher yield in the following lactation period.

1084. Calving time.—Unless the herd is at pasture, the cow should be put in a thoroughly cleaned and disinfected box stall at least 2 or 3 days before the expected date of calving. Even when the cows are on pasture, it is wise to put a cow that is soon to calve in a box stall or in a small pasture lot where she can be given any needed attention.

As calving time approaches, the udder of a good cow will become swollen with milk, and in some cases may become decidedly congested. Some dairymen start milking such cows a few days before calving (called prepartum milking), in the belief that it will reduce the swelling and congestion. However, in experiments in which prepartum milking has been tested, in most cases it did not have this effect.[25] In these experiments prepartum milking did not generally increase the milk yield in the following lactation.

When a cow is milked prepartum, it is necessary to save for the calf, by freezing or refrigeration, the colostrum milk that will be produced mostly before the calf arrives, or else to feed it colostrum from another cow, or to feed it a vitamin A supplement. (1117) If the udder becomes unduly congested, it is well to rub it twice a day with a mixture of one-half cod-liver oil and one-half ethyl alcohol, or some other suitable mixture.

The cow may be allowed feed and water as usual up to calving time, but she will not generally have much appetite soon before calving. She should not be molested during calving, unless assistance is needed. To avoid injuring her, assistance should then be given only by a veterinarian or some other experienced person. During and after calving, the cow should be protected from drafts.

As soon as the calf arrives, it should be given any needed attention. If it does

not begin to breathe promptly after birth, any mucus or membrane should be removed from its nostrils, and attempts should be made to start respiration by slapping the chest vigorously or by alternately compressing and relaxing it.

If the cow does not dry the calf by licking, it should be dried by rubbing with a cloth or dry straw. If the afterbirth is not expelled naturally within about 48 hours after the birth of the calf, the services of a veterinarian should be secured, if possible. The cow should not be allowed to eat the afterbirth.

If the calf is weak and does not nurse within a half hour, it should be helped to get its first meal. It is very important that the calf receive the colostrum. (270) To guard against navel infection, the navel should be disinfected with tincture of iodine soon after birth.

It is best to separate the calf from the cow not later than 24 hours after birth.[26] If left with her longer, it may get so much milk that scours will result. It is also usually less difficult to teach a calf to drink from a pail when it is separated from its dam not more than a day after birth, than when it remains with her longer.

1085. Feed and care after calving.—It is highly important that a cow be properly fed and cared for during the first month after calving. Because of her weakened condition, she should be blanketed after she calves, if the stall is too cold. The amount of feed should be very limited for the first day, and the cow should be given lukewarm water to drink, unless there is a drinking bowl in the stall. During the first day after calving she may be given what hay and other roughage (including silage) that she cares for, but she should have only a small amount of grain mixture. If the cow is doing well, she may have for the first feed about 1 lb. of the same concentrate mixture that was fed during the dry period. Some dairymen prefer to feed a cow a hot bran mash or a mash of bran and oats, fed as a slop, soon after calving.

After the first day, the amount of grain mixture should be increased grad-

ually until the cow is on full feed. However, where there has been trouble from ketosis in a herd, it is important to get cows on full feed as soon after calving as can be done without throwing them "off feed." (1087) It may take 3 weeks or more to get high producers on full feed, while lower producers can be fed their usual allowance somewhat sooner.

If the udder of a cow becomes swollen and congested, the amount of grain mixture should be reduced. Applying cold water carefully to the udder with a hose, followed by thorough milking, will relieve the congestion. This process should be repeated 4 to 6 times a day, if necessary.

1086. Milk fever.—Dairymen with experience know that their best cows, except heifers, are apt to have milk fever during the first few days after calving. This is caused by a lack of calcium in the blood, produced by the heavy drain on the supply of this mineral when the cow begins to secrete a large amount of milk. It has been stated previously that the parathyroid glands normally regulate the amount of calcium in the blood in some manner. (**54**) Later in lactation the cow is able to draw on the store of calcium in her skeleton when she does not secure enough from her food. At the outset of lactation the parathyroid glands seem to be unable in some cases to meet the demand for calcium, and milk fever results.

The incidence of milk fever, or parturient paresis, is highest in high-producing cows 5 to 10 years old, and Jerseys are more susceptible than other breeds. First calf heifers are rarely affected.

The usual treatment for milk fever is the injection of a solution of calcium gluconate or other calcium salt into the jugular vein or mammary veins, to raise the calcium content of the blood. The older method of treatment was to inflate the udder with air, which stops milk secretion by the increased pressure in the udder, and thus prevents the drain on calcium for milk production. The method is effective, but there is danger of infecting the udder with mastitis. However, the inflation method is still used in cases which are not cured by the injection of a calcium salt.

Some dairymen follow the practice, in the case of high-producing cows, except heifers, of leaving some milk in the udder at each milking for a few days after calving, in order to reduce the milk secretion. Others believe that prepartum milking lessens the tendency for milk fever to develop. However, in Mississippi and Wisconsin tests partial milking was not effective in preventing it,[27] and neither was prepartum milking in Wisconsin trials.[28]

In recent Ohio experiments milk fever has been prevented in susceptible cows by giving in the feed extremely large doses of vitamin D daily for at least 3 days and preferably not more than 7 days before calving, and 1 day after calving.[29] The daily dose is 30 million units of vitamin D in the form of dry irradiated yeast or else irradiated ergosterol in oil. This dosage should not be continued for a longer time, as this great amount of vitamin D is toxic if continued too long. If a cow does not calve by the expected time, the dosage should be discontinued until she calves, and the treatment given again for the day after calving. The high dosage of vitamin for the short time seems to prevent the drop in the calcium content of the blood, either by increasing the assimilation from the food or by mobilizing the calcium store in the skeleton.

Another method of prevention recently developed through California experiments is to feed susceptible cows a ration very high in phosphorus and extremely low in calcium for a month before calving.[30] In this method the cow is fed only 5 to 8 lbs. a day of low-calcium hay, such as oat hay or grass hay with no legumes, and is allowed no other roughage. She is fed 8 to 12 lbs. a day of a low-calcium concentrate mixture to which is added 5 lbs. of sodium phosphate per 100 lbs. of the mixture. It is believed that this method of feeding forces the parathyroid gland to increase its activity and draw on the calcium store in the skeleton.

This method of prevention was ef-

fective in most cases. However, it has the disadvantage that high-producing cows can regain their store of calcium, lost during the height of milk production, only during the dry period and the last part of the lactation. Where this method is tried, it is important that the cows get an abundance of legume forage, high in calcium, during the latter part of the lactation period and during the first part of the dry period, before they are placed on the calcium-deficient ration.

1087. Ketosis, or acetonemia.—Ketosis, or acetonemia, is a serious disease in some dairy herds, especially of high-producing cows. Some of the symptoms resemble milk fever, but it does not usually occur until several weeks after calving. In ketosis there is a rapid fall in milk yield, a loss of weight, digestive disorders, drowsiness, and sometimes pronounced nervous symptoms.

Ketosis is apparently caused by an insufficient supply or faulty utilization of carbohydrates in the body, resulting in a serious deficiency of glucose in the blood. The trouble may be brought on by various causes or stresses, but the chief cause is the drain on the glucose supply of the blood in high production. The lack of carbohydrates causes an increased metabolism of fat, and an accumulation of certain normal products of fat metabolism (called ketone bodies) which are toxic when present in excess. The disease has usually been treated by the injection of a glucose solution into a vein, generally combined with the feeding of molasses or sugar.

Recently, Shaw and associates of the Maryland Station have found that ketosis can be cured, except in cases complicated with other diseases, by the intramuscular injection of the hormone cortisone.[31] Sometimes a second or third injection is needed. The hormone called ACTH (or corticotropin) has also been used with success. Certain cortisone derivatives are even more potent than cortisone. These hormones restore the blood level of glucose.

Still more recently, Schultz of the New York (Cornell) Station has had good results in curing uncomplicated cases of ketosis by feeding sodium propionate, a relatively cheap compound, for 3 to 10 days at the rate of one-quarter pound daily, divided into two doses, mixed with the grain.[32] In severe cases where the cow is eating little or no grain, one-half pound of the sodium propionate is administered by capsule or drench.

In a test with 50 pairs of cows, one in each pair fed sodium propionate and one not, Schultz has also had good results in preventing ketosis by feeding one-quarter pound of it per head daily in the grain mixture for 6 weeks after calving.

Certain other products may help to prevent ketosis, but more data are needed to warrant conclusions concerning their effectiveness.

Insufficient feed before or after calving may tend to produce ketosis. It is therefore not advisable to reduce the amount of concentrates too much before calving, and it is best to increase the feed intake after calving as rapidly as is safe. Some feed molasses or another form of sugar for 2 or 3 weeks after calving, but this is of doubtful value as a preventive of ketosis. Tests have shown that supplements supplying vitamin A, the B-complex vitamins, cobalt, or choline are not effective in preventing or curing ketosis. There may be more trouble from it when the cows have only poor roughage, such as cottonseed hulls.

IV. Care of the Milking Herd

1088. Shelter and comfort.—On dairy farms in the northern states the cows are generally housed during winter in closed stables, and confined by stanchions or sometimes by ties or in stalls. The cows are kept in the stable, except that they are usually turned out for exercise in suitable weather for an hour or so a day. During the pasture season the cows are commonly outdoors, except at milking time.

Well-fed dairy cows do not need warm quarters in winter, even in cold climates. This is because they are kept warm by the large amount of heat produced in their bodies in the digestion

and utilization of their liberal rations. (228) Even in severe winter weather in the northern states, there is no benefit from a higher temperature than is provided by a well-built stable which is thoroughly insulated and has an efficient ventilating system.

It was concluded in a national survey of requirements for dairy barns that stable temperatures not lower than 35° to 45° F. were satisfactory in winter for dairy barns in the northernmost states.[33] It was advised that the barn should be ventilated so that the relative humidity of the air did not exceed 75 per cent under average weather conditions and 85 to 90 per cent on extremely cold days.

In studies by the United States Department of Agriculture and the Wisconsin Station it was found that the optimum winter stable temperature for cows in stanchions and moderately well fed was about 50° F.[34] There was very little decrease in milk production at 45°. At 60° to 65° the milk yield was above average, but the fat percentage was slightly reduced and the cows seemed less comfortable. At the higher temperature there was much more trouble from cowpox. The lower temperature was preferred by the milkers, and the stable odors were less pronounced.

Even in cold winter weather, well-fed dairy heifers over a year of age thrive when housed in an open shed, protected from prevailing winds. Many experienced dairymen believe that heifers housed thus and allowed to run out at all times into an exercise paddock are apt to develop into more rugged cows than heifers which are confined to a warmer stable in winter and allowed less exercise.

Though housing yearling heifers in an open shed is excellent from the standpoint of the thrift of the heifers, experiments indicate that in cold climates heifers thus housed may require considerably more feed than those in warmer quarters. This is because dairy heifers are fed less liberally than cows in milk, and therefore less surplus heat is produced in their bodies.

In Maine, North Dakota, and South Dakota trials heifers housed in an open shed or in a barn with an open door, through which they could run in and out, gained less and required considerably more feed than others housed in a warmer barn.[35]

For the comfort of dairy cows swinging stanchions are much preferable to the old-fashioned rigid ones. Many stanchion-type dairy barns have platforms too short and space for each cow too narrow for the larger cows in the herd. In such a barn udder and other injuries are more frequent.

Especially with long stalls, electric cow trainers keep the cows cleaner.[36] This device is suspended just above the cow's shoulders and is connected to an electric fence controller. When she humps up her back to defecate, she gets a very mild electric shock and steps back, so that the droppings fall in the gutter, instead of on the platform.

High-producing cows may yield slightly more milk when they have the freedom of individual box stalls, instead of being confined in stanchions. However, this increase, which will probably be less than 4 per cent, is not enough to pay for the extra labor and bedding required and the extra cost of housing, except in the case of cows on advanced registry test.[37] In a West Virginia experiment cows kept cleaner and had fewer injuries in "comfort" stalls than in tie-chain stalls which were smaller.[38] There was no difference in the amount of bedding needed.

For the comfort of the cows and for cleanliness, sufficient bedding should always be used. The various common bedding materials are discussed in Chapter XXIV. So that milk of good sanitary quality can be produced, the barn and the cows should be kept clean. Though grooming the cows may not increase the yield of milk appreciably, it is important from the sanitary standpoint. (1066)

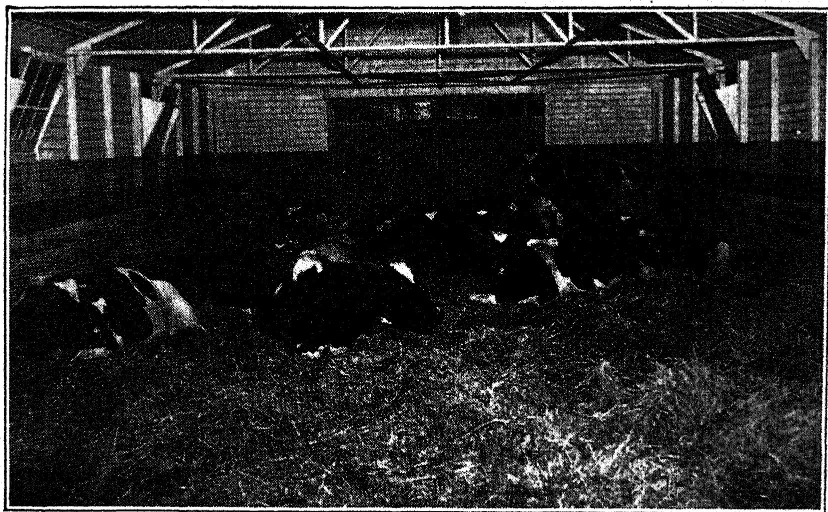
The importance of an efficient ventilating system to provide fresh air, to maintain a proper temperature, to reduce the humidity, and to remove dampness and foul odors, has been emphasized previously. (246) For proper light, there should be a sufficient area of windows,

well distributed in the stable. A common rècommendation has been 4 square feet of glass area per cow, but in cold regions 3 to 3.5 square feet per cow is sufficient. The smaller glass area cuts down the loss of heat from the stable in winter.

It is well to disinfect the stable thoroughly at least once each year, to aid in checking any possible spread of disease. The benefits from dehorning cows have been pointed out in the previous chapter.

fed their grain. The hay and other roughage is best fed in a paved area adjacent to the loafing area. This is not bedded, but is cleaned daily or frequently. The loafing area is kept well bedded and is cleaned only when the manure has accumulated to a considerable depth. Much more bedding is needed to keep the cows clean than when they are housed in a stanchion barn.

The loafing-shed and milking-room system has certain definite advantages and also certain disadvantages. In the



LOOSE HOUSING SYSTEM OF HOUSING COWS

The cows have the freedom of an open shed, except at milking time, when they go in relays to a milking room. (From Wisconsin Station.)

The hoofs of dairy cattle should be trimmed when necessary to prevent them from becoming so long that the feet are injured. When the cattle are on pasture, the hoofs generally wear down sufficiently, but during the winter trimming is often necessary.

1089. Loose-housing.—During recent years many dairymen have adopted the loose-housing, or pen-barn, method for their dairy cows. In this system the cows have the freedom of an open loafing shed or a large stable with a door open to the outside, except at milking time when they go in relays to a milking parlor. Here they are milked and usually

loafing-shed method the cows are more comfortable and there are fewer injuries to udders, hocks, and knees. The cows keep cleaner, if enough bedding is used. The trouble from mastitis may be reduced. When the manure is allowed to accumulate in the pen barn and is only cleaned out a few times each winter, losses in fertility value can be lessened. (995) It is much easier to detect heat periods in the cows, but cows in heat may disturb the rest of the cows. The herd may be increased in size more readily, by building a cheap addition to the shed. The stable may easily be adapted to other types of livestock. If a new build-

ing is to be built, the cost of housing will be less with this method.

The chief disadvantage is the much greater amount of bedding that is required to keep the cows clean. Where there is a shortage of bedding, this may be a very serious disadvantage. There are also other disadvantages. In the loafing-shed method of housing, boss cows are often troublesome. Sometimes, certain cows must be housed elsewhere or disposed of for this reason. The cows must be dehorned in this method. In cold climates it is necessary to heat the milking room and also preferably the quarters for young calves the first few weeks of their lives. The cows grow heavier coats of hair, and the herd does not show off so well to men who may wish to purchase dairy animals. Disease may spread more rapidly in this method of housing. In some market milk areas, the health regulations may not permit this method of housing dairy cows, though milk of very satisfactory quality can be produced by it if a proper amount of bedding is used.

Even in the extreme northern states, in the several tests of the loose-housing method by the experiment stations there has been little or no difference in the feed required by cows thus housed and those in much warmer ordinary stables.[39] This is because of the surplus heat produced in the bodies of well-fed cows in digesting and utilizing their liberal rations. Also, although the air temperature in the loafing shed may be very low in winter, the temperature in the manure just below the straw bedding is always warm, ranging between 70° and 100° F., regardless of the weather. This is due to the heat produced in the slow fermentation of the mass of manure. The cows therefore always have a warm bed to lie upon, even in zero weather.

1090. Flies and fly sprays.—Every dairyman should endeavor to rid the premises of flies as much as possible. Flies not only annoy the cows and attendants, but are also a source of contamination. Control of flies by spraying has become more difficult because in some areas the flies have become resistant to lindane and methoxychlor, the two chief residual sprays approved for use in dairy stables.

The most effective method of fly control is therefore preventing their breeding by careful cleanup of all possible breeding sites. Pens and boxstalls should be cleaned at least twice a week in summer and the manure should be spread immediately or put at a considerable distance from the dairy barn. House flies can travel at least 2 miles.

For spraying a dairy stable an insecticide should be used which is approved by the Food and Drug Administration for such use, instead of using an insecticide such as DDT, which passes into the milk, thus contaminating it.

The sharp decline in milk production which often occurs in midsummer is sometimes attributed to the annoyance of the cows by flies. Investigations have indicated, however, that in most dairy regions the decline is usually due more commonly to the heat or to a scanty supply of pasturage at this time.

For spraying dairy cows, one should use a pyrethrum spray, or one of the other sprays approved for this purpose. In numerous experiments, spraying cows with the older-type commercial or home-mixed fly sprays usually made little or no increase in milk yield.[40] In some tests heavy applications of oil fly sprays even caused a decided drop in milk yield, especially in hot weather. This was probably because the film of oil on hair and skin raised the body temperature in hot weather by preventing the evaporation of water from the skin. Some fly sprays may temporarily injure the parts of the skin exposed to the sunlight, if applied daily over a considerable period. For calves a water-emulsion or wettable-powder spray should be used, as oil-base sprays may produce serious skin injury, somewhat similar to X-disease.[41] Medicated stock salts, sold as a fly repellent, were found ineffective in Kansas and Oklahoma tests.[42]

1091. Exercise.—Except in stormy or unusually cold weather, dairy cows should be turned out daily during winter for exercise in a sunny yard sheltered

from prevailing winds. This will aid in keeping them thrifty, and the exposure to sunlight will help provide vitamin D. Moderate exercise also tends to increase slightly the yield of milk and the percentage of fat. (**1066**) Forcing cows to stay outside a good share of the day in cold weather wastes feed and may reduce the yield severely. In the South, winter pasture should be provided whenever possible, in order to reduce the cost of feeding the herd.

1092. Frequency and order of feeding.—The most common practice in dairy herds is to feed the grain mixture before milking, and then after milking to feed the silage or other succulent feed which might taint the milk if fed before milking. When the cows are milked in a milking parlor, usually the cows are fed their grain mixture at that time. The hay is generally fed after the silage has been cleaned up. With cows milked more than twice a day, part of the daily allowance of grain mixture is usually fed before each milking and the hay and silage only at morning and night. If one wished to have the cows eat the maximum amount of hay, the hay consumption can be increased somewhat by supplying fresh hay more than twice a day.

Hay and other dry forages should not be fed until after milking, as they are apt to fill the air with dust. Also, alfalfa hay may produce a marked flavor in milk if fed less than 4 hours before milking.

The particular order of supplying the various feeds is not important, but the same order should be followed from day to day and the cows should be fed and milked at regular times. A lack of regularity is apt to decrease the yield of milk and fat somewhat.

Some dairymen put the grain mixture on top of the silage in the manger, and this is a good plan if one is feeding a liberal allowance of a heavy mixture, containing no bulky feeds. Cows which are accustomed to getting their grain before milking may tend to be restless and "hold up" their milk if the grain is not fed until after milking, but it will not take them long to get used to the change.

It is sometimes advocated that dairy cows be fed only once a day, so as to save labor.[43] However, in a trial of this method by the United States Department of Agriculture, cows fed twice a day ate 10 per cent more alfalfa hay, produced 6 per cent more milk, and gave a greater net return over cost of feed and labor, than when fed only once a day.[44]

1093. Milking.—Extensive recent investigations have proved the great importance of proper milking of dairy cows. In particular, these studies have shown that rapid milking not only saves much time, but also reduces the trouble from mastitis and even tends to increase the yield. This is due to the following interesting facts:[45]

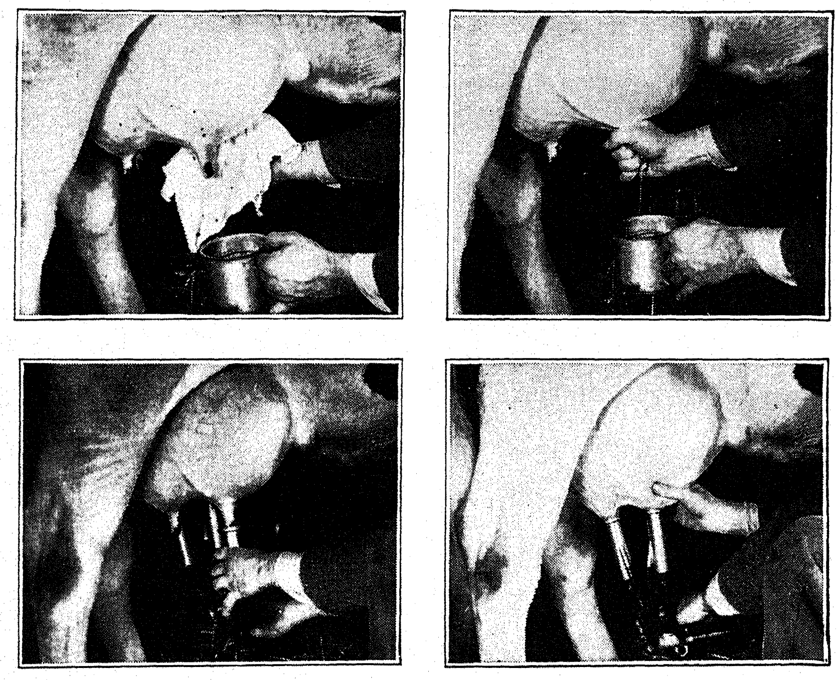
As has been pointed out in Chapter X, the secretion of milk is a continuous process and most of the milk secured at each milking is present in the udder when milking starts. However, only a small part is in the milk cistern and the large ducts. Most of it is held in the millions of tiny alveoli and in the small ducts. These are so small (each alveolus holding only a fraction of a drop) that the milk is held firmly by capillary action. It cannot be removed by the suction of machine milking or by the pressure of hand milking.

However, if the proper stimulus occurs, the cow "lets down" her milk. This is not a voluntary action on the part of the cow, but a reflex or automatic one caused by a hormone which is secreted by the pituitary gland at the base of the brain.

When the proper stimulus takes place, nerve messages are carried to the cow's brain, causing the hormone, called oxytocin, to be ejected into the blood. It is then carried to the tissues of the udder where it causes muscular fibers surrounding the alveoli and small ducts to contract. This squeezes the milk into the larger ducts and the milk cistern, and we say the cow has "let down" her milk.

The effect of the hormone lasts only a few minutes. Therefore the largest yield of milk is secured when the cow is milked rapidly, before the smaller muscular fibers relax.

If the cow becomes excited or frightened, another hormone called adrenalin, which is produced by the adrenal glands, has the opposite effect. It interferes with the oxytocin. Then we say that the cow has "held up" her milk, because the milker can get only the small amount the water. The udder of a cow should not be washed more than 1 to 3 minutes before milking is to start, for it takes even less time than this for the action of oxytocin to cause the "let down" of the milk. If the start of milking is delayed too long, the effect of the oxytocin may



STEPS IN EFFICIENT MACHINE MILKING

Upper left: Stimulate the cow to let down her milk by washing her udder with warm chlorine water one minute before putting on the machine.

Upper right: Check each quarter for mastitis by using a strip cup.

Lower left: Put on the teat cups about one minute after preparation.

Lower right: Strip the cow by machine. When the teat cups start to crawl up on the udder, they should be pulled part way down, using the free hand to massage the udder. Short-tube machines may not need this downward pull. (From New York State College of Agriculture, Cornell University.)

already present in the milk cistern and large ducts.

Cows usually like to be milked, and anything which is commonly associated with the milking process may cause them to "let down" their milk. Thus, cleaning the udder with a cloth or paper towel wet with warm water is an effective way of providing the stimulus. For sanitary reasons chlorine or a quaternary ammonium compound should be added to not last, and the cow may "hold up" her milk. If some cows tend to "let down" their milk as soon as milking starts in the barn, they should be milked first.

These recent studies provide an interesting explanation for the well-known fact that regularity in feeding and stable management is necessary to secure the largest yields from good cows. Also, the kind milker who gains the confidence of

cows secures more milk from them than a rough or indifferent person.

Incomplete milking tends to reduce the milk yield,[46] and it may increase trouble from mastitis in cows whose udders are infected with the disease. However, it must be remembered that milk secretion is a continuous process. Therefore a cow can never be milked "bone dry."

1094. Machine milking.—Because of the saving of labor and also the difficulty of securing good hand milkers, milking machines have come into common use on our larger dairy farms. Extensive trials by the experiment stations show that satisfactory results, both in yield and quality of milk, are secured when good milking machines are handled by careful operators, who use proper methods of milking and who thoroughly cleanse and sterilize the equipment. When the newer method of rapid machine milking is properly used, the production is equal to good hand milking, and the trouble from mastitis is no greater.[47] On the other hand, with the older method of machine milking in which it often took 9 to 10 minutes per cow, the production tended to be less than from first-class hand milking and trouble from mastitis was greater.

To secure the best results by machine milking, certain rules must be carefully followed: [48] (1) The cow should be stimulated to let down her milk by washing her udder with warm water 1 to 3 minutes before putting on the machine. (2) The machine should be operated according to the manufacturer's directions. Increasing the vacuum or altering the rate of pulsation may make milking unpleasant for the cow. (3) The cows should be stripped by machine. When the teat cups start to crawl up on the soft tissues, they should be pulled part way down, using the free hand to massage the udder. Pulling the teat cups down prevents a pinching action which would shut off the milk ducts leading into the teats, and thus cause incomplete milking. (4) Do not leave the machine on the cow after milk stops flowing. Leaving it on longer may congest the delicate tissues and lead to mastitis.

If this routine is followed, most cows will milk out sufficiently clean in 3 to 4 minutes without any hand stripping, except perhaps a few squeezes on each teat to see if the quarter has been milked clean.

In cost accounting studies on dairy farms the amount of total man labor per cow a year has usually been 18 to 31 hours less per year in herds where milking machines were used than where the cows were milked by hand.[49] The time needed for milking can be reduced still more by the use of a modern milking parlor.

Care must be taken not to spread mastitis by the use of a milking machine. The teat cups should be rinsed and then dipped in a chlorine solution before being placed on the next cow. Cows having mastitis should always be milked last.

1095. Hand milking.—The same method of stimulating the cow to let down her milk should be followed in hand milking as in machine milking. She should then be milked as rapidly as possible.

It is always desirable to have the same man milk each cow at every milking, but a change will not usually affect the yield of milk appreciably, if the new man is as good a milker as the former one.[50] Regularity in the time of milking is highly desirable, especially in the case of high-producing cows. However, cows of average production can apparently be milked with occasional irregularity without any appreciable decline in yield, provided they are fed regularly.

In milking cows thoroughly so as to get all the strippings, the best milkers generally manipulate the udder to some extent toward the end of milking. An upward pressure on each quarter for a few times when milking is nearly completed helps to bring the last milk into the teats, where it can be drawn. More elaborate methods of massaging and manipulating the udder are not necessary.[51]

1096. **Regularity and kindness.**—Regularity and kindness are even more important with dairy cows than with other farm animals. The highest-yielding cows are usually of nervous temperament, and especially with such animals, excitement often causes a sharp decrease in yield. Cows being driven should not be hurried, and attendants should never strike or otherwise abuse them.

Good dairymen now realize the fact brought to public attention by W. D. Hoard of Wisconsin that dairying is based on the maternity of the cow, and treat their animals accordingly. As Haecker wrote: "If you so handle the cows that they are fond of you, you have learned one of the most important lessons that lead to profitable dairying. . . . A cow's affection for the calf prompts the desire to give it milk; if you gain her affection she will desire to give you milk." [52]

V. The Cost of Milk Production

1097. **Determining the cost of milk production.**—Many investigations have been conducted by the experiment stations to find the cost of milk production in the various states. These studies have not only furnished much information on this important subject, but have also shown how a farmer can reduce his own costs and increase his net returns, or even convert a loss into a profit.

In determining the cost of milk production the expenses are commonly grouped as follows:

(1) The combined cost of feed and bedding is by far the largest single item of expense, generally forming from one-half to two-thirds of the total cost. This expense will vary widely, depending on the prices of feeds, the average production of the herd, and the economy of the rations used.

(2) Next in importance is the cost of man labor in milking and feeding the cows, cleaning the stables, handling and hauling the milk, etc. This makes up at least one-fifth the total cost. Commonly, all the man labor is figured at the current rate for farm labor. Then an item is sometimes added to cover managerial ability and business risks, a common estimate for this being 10 per cent of the other total costs.

In addition to these two main expenses, the following must be included: (3) The building charge, which includes interest, insurance, depreciation, and repairs on the part of the barn occupied by the cows and by storage for their feed; (4) the equipment charge, which covers cost of milk utensils or machinery, tools, etc.; (5) the cow charge, which covers depreciation, interest, taxes, and mortality risk on the cows; (6) the pro-rata cost of keeping the sire or the cost of breeding service; and (7) miscellaneous expenses, including cash paid for hauling milk, horse and tractor labor, cost of supplies, veterinary services, cow-testing association fees, etc.

The depreciation charge is a larger item than often believed, because the average useful life of dairy cows in the herd after they first calve has been found to be only 4 to 5 years.[53] While many cows have a much longer useful life, the cows are replaced within this period, on the average, because of low milk yield, failure to breed, injury, or disease.

Where most of the replacements are purchased instead of being raised on the farm, the productive life of the cows in the herd is usually much shorter. For example, in a study of Connecticut dairy herd improvement association herds, it was found the average productive life of the cows in herds where the replacements were purchased was only 2.6 years, while it was 5 years in herds where the replacement heifers were raised on the farm.[54]

The annual depreciation may be estimated by computing the difference between the cost or value of the cow when she first calves or is purchased and the price she will bring when discarded, and dividing this difference by her number of years of production in the herd. For example, if a cow is worth $200 when she first calves, then has a useful life of 5 years, and finally brings $110 when sold for beef, the annual depreciation

will be one-fifth of $90, or $18. The mortality risk is not large, when the health of the herd is properly safeguarded, being only about 1.5 per cent a year.

From the total gross cost of keeping the cows there must be deducted the value of the manure and the value of the calves at a few days of age. The value of the calves will of course vary widely, depending on their breeding. In studies of the cost of milk production where some of the herds include purebred cows, these are usually valued at the price of grades of similar productive capacity, and the calves credited at veal or grade prices. This is done so as to differentiate between the financial returns from producing milk and from breeding purebred cattle.

1098. Annual cost of keeping cows.—Many studies have been made of the cost of milk production on dairy farms. The method by which the cost is determined is shown in one of the most recent studies, on 113 farms in dairy districts of west-central New York for 1953–54.[55] On these farms the average milk production per cow was 8,439 lbs. of milk and 312 lbs. of fat. The feed consumption per cow for the year averaged: Home-grown grain, 1,946 lbs.; purchased concentrates, 1,036 lbs.; hay, 2.4 tons; silage, 5.3 tons; and pasture during the season.

The costs per cow were: Feed, $207.04; labor, $101.72; building charge, $15.11; equipment charge, $9.06; depreciation on cow, $16.16; interest on value of cow, $10.82; breeding cost, $6.00; bedding, $10.21; milk hauling, $17.87; and miscellaneous, $15.45; making the total gross cost per cow $409.44.

From this was deducted a credit of $11.38 for calves and of $10.50 for the value of the manure. This made the net cost $387.56 per cow, or the net cost per 100 lbs. of milk $4.59.

The following table shows the average milk yield per cow and the amounts of feed and labor required in studies in other dairy districts.[56]

It will be noted that the annual milk production per cow in these studies was decidedly higher than the average yield in this country.

Feed and labor required by dairy cows

	Michigan	Illinois	North Carolina	Washington
Av. yield per cow				
Milk, lbs. . . .	8,186	8,328	6,318	. . . .
Fat, lbs.	303	302	275	308
Feed and bedding				
Concentrates, lbs.	2,840	2,352	2,961	2,060
Hay, lbs.	4,343	2,552	3,051	5,400
Other dry roughage, lbs. .	503	311	480	*
Succulent feeds, lbs. . .	5,078	7,048	4,497	3,400
Pasture, days	149	160	*	*
Bedding, lbs.	*	880	*	*
Labor				
Man, hrs. . . .	132	118	184	163

* Amount not stated.

1099. Formulas for estimating cost of milk production.—Various simple formulas are sometimes used for estimating the cost of milk production. In these formulas all the costs are reduced to terms of feed and labor. Therefore, by taking the current prices for feeds and for labor, a more or less approximate estimate of the cost of producing milk can readily be made at any time. In using these items as a basis for calculating the cost of producing milk, it is assumed that as the prices of feeds and labor rise or fall the other items of expense and the credit items will change accordingly.

The way in which such a formula is used is illustrated by a recent formula for estimating the cost of producing milk in the market-milk districts supplying the New York metropolitan area.[57] This region covers most of New York State and extends into adjoining states.

According to this formula, the cost of producing 100 lbs. of milk in this region may be estimated by first totalling the cost of 33 lbs. of concentrates, including home-grown grain; 71 lbs. of hay and other dry roughage; 128 lbs. of silage; 2.3 days of pasture; and 2.5 hours of man labor. This total represents about 80 to 85 per cent of the total net cost, depending on the price level of feeds

in relation to other costs. Therefore it must be increased accordingly to find the estimated total net cost of producing 100 lbs. of milk.

To illustrate the use of the formula, let us assume that the cost of a good concentrate mixture, including some home-grown grain, is $65 a ton; of hay, $20 a ton; of silage, $8 a ton; of pasture, 7 cents per cow a day; and of farm labor, 65 cents per hour, including board. At these prices, the total cost of feed and labor according to the formula will be $4.08 per 100 lbs. of milk. If this is 85 per cent of the total net cost, the total cost is found by dividing $4.08 by 85 and multiplying the quotient by 100. This will give us $4.80 as the estimated total yearly cost of 100 lbs. of milk at the prices stated for feed and labor.

1100. Seasonal cost of production.—Every experienced dairyman knows that it costs much more to produce milk in winter than in summer when the cows are on pasture. This is because pasture is a cheap feed, and also because much less labor is required in producing each 100 lbs. of milk when the herd is on pasture than under winter feeding conditions. The difference in cost between winter and summer is well shown in studies on the cost of milk production in 5 New York counties.[58] Charging man labor at a uniform rate throughout the year, the cost of milk production was 82 per cent greater from October through March than in the period from April through September.

Since it costs less to produce milk in the summer, the natural tendency will be for dairymen to concentrate production in the more profitable months by having their cows freshen in the spring. Therefore in order to secure a steady supply of milk for city consumption, the price paid farmers in market milk districts must be enough higher in winter than in summer to offset the difference in cost of production.

It has been shown in the previous chapter that the annual yield of milk is somewhat larger from cows calving in fall or early winter than from those freshening in the spring or summer. (**1061**) However, where milk is produced for butter or other manufactured products in districts far from the metropolitan areas, summer dairying may be most profitable, because of the low cost of production on pasture.

1101. Reducing the cost of milk production.—The studies of the cost of milk production have shown that the following are the most important factors in reducing the cost:

1. *Large average yearly yield.* It has been emphasized in the previous chapter that a large average yearly yield per cow is the most important factor affecting the cost of milk production. (**997**) To secure this, the dairyman must first of all have good cows and then cull his herd each year to get rid of unprofitable animals. (**1005**) Next, he must feed and care for these good cows so they are given full opportunity to yield a profitable amount of milk.

2. *Balanced rations.* Cows of high productive capacity cannot produce a good yield unless they are fed adequate rations, properly-balanced in protein and supplying ample minerals and vitamins. It has been clearly shown in the studies of the cost of milk production on dairy farms that a lack of protein seriously reduces the yield of milk and consequently the net returns.

3. *A liberal but not wasteful amount of feed.* A large yield of milk is impossible without a liberal supply of feed, as has been emphasized previously. However, wasteful feeding of concentrates must be avoided at all times. Therefore the amounts fed to the individual cows should be strictly adjusted to their milk yields.

When concentrates are very expensive in comparison with roughage, it is most economical to feed less concentrates than are needed to meet the recommendations of the feeding standards. It is then especially important that the roughage be of excellent quality and that it be fed with great liberality. (**1029**)

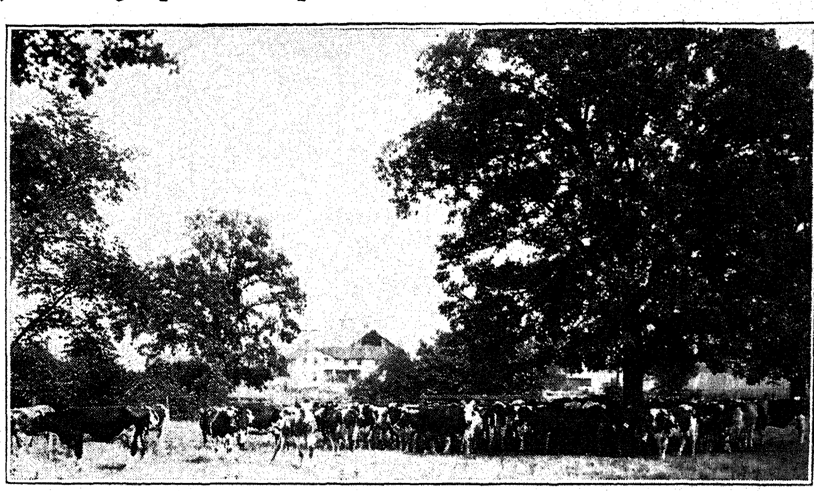
4. *Low-cost rations throughout the year.* To keep the feed cost as low as possible and yet secure high production, good yields of crops of the best feeding

value must be raised. The cost of efficient rations during the barn-feeding season can generally be kept at a minimum by providing an abundance of legume hay or of mixed hay high in legumes, along with good silage where silage is an economical feed. (**1022**) With such roughage it is not necessary to feed as much concentrates to secure high production, as when the roughage is poorer.

For economical summer feeding, it is necessary to provide excellent pasture over just as long a period as is possible. Enough concentrates must be fed in addition to keep up milk production and prevent the cows from running down in condition. If pasture becomes scanty, it must be supplemented by feeding silage, hay, or soiling crops. (**1079**)

5. *Maintaining herd health and avoiding heavy depreciation.* Unless great care is taken to prevent disease and maintain the health of the herd, disease will destroy all possible profits. It is especially important to avoid losses from Bang's disease (infectious abortion) and to handle the cows so that mastitis is reduced to a minimum.

The necessary replacements for the milking herd can usually be provided most economically by raising properly the heifer calves from the best cows in the herd, sired by a bred-for-production purebred bull. In dairy districts where the cost of feed is not unduly high, many farmers reduce the cost of depreciation to a minimum by selling cows when they are in their prime and will bring a good price, instead of waiting until they must be discarded as culls. They replace these animals with good heifers which they have raised. Careless dairymen may sometimes raise just as many calves for replacement, but because of disease and poor management, never have any cows to sell except culls.



ENOUGH COWS SHOULD BE KEPT TO MAKE AN ECONOMICAL UNIT

If dairy cows are to provide the main source of income on the farm, a sufficient number must be kept to make an economical unit. The exact number should depend on the local conditions.

6. *A herd of sufficient size.* If dairy cows are to provide the main source of income on a farm, a sufficient number must be kept to make an economical unit. If there are only a few cows in the herd, the gross income will necessarily be small, labor will be employed less efficiently, and if a bull is kept, the bull cost per cow will be greatly increased.

7. *Efficiency in the use of labor.* Many dairymen do not fully realize the importance of efficiency in the use of labor to reduce the cost of milk production. There is a great range in the num-

ber of hours of labor spent in feeding and caring for the cows on individual farms, even where the milk is of the same quality from the sanitary standpoint. To reduce the amount of labor the barn must be arranged conveniently and labor-saving equipment must be provided, such as drinking bowls, grain cart, and silage cart. As has been pointed out in this chapter, the loose-housing method saves considerable labor. Also, labor is considerably reduced by the rapid milking method and by the use of a milking parlor. In a large herd an automatic barn cleaner saves enough hard labor to be a good investment.

Considerable time can be saved by efficient planning of the daily routine and convenient location of tools and supplies. The great saving of labor that can often be made is shown by the results secured by a New England dairyman who was already an efficient farmer.[59] This is evident from the fact that he alone did all the work on his 150-acre farm and cared for his herd of 22 cows, except for an extra man for about a month a year. By rearrangement of the stable, providing labor-saving but inexpensive equipment, better location of tools and supplies, and improvement in the work routine, the time spent on chores was reduced from an average of 5 hours 44 minutes a day to only 3 hours 39 minutes. The daily travel in doing the chores was cut from 3.25 to 1.25 miles a day. These savings would mean in a year more than 2 months of time and 730 miles of walking.

VI. Feeding and Caring for Cows on Official Test

1102. Cows on official test.—The feeding and management of cows fed for maximum production on official test is fully as much an art as a science. The completion of a notable record depends largely upon the intelligent feeding and painstaking care of an expert herdsman. The rations and methods used by leading breeders differ widely. In fact, nearly every champion cow has received a somewhat different ration from other record-breaking cows. This indicates that there are no secret formulas or methods of management which are outstanding in their superiority over all others.

The following brief summary on the feeding and care of test cows is presented with the hope that it may be helpful to those who have not had experience in this field.[60]

1103. Fitting cows for official test.—The highest production of which a cow is capable can be secured only when she is well fitted, or fattened, before she freshens. When a cow calves in high condition, her production of milk and fat is considerably increased during the early part of her lactation, because she can draw on the store of fat in her body. (**1062**) Also, in the case of cows of the lower-testing breeds, the richness of the milk is generally raised to a marked extent during the first few weeks of lactation.

A cow that is to be run on official test should be completely dry about 60 days before she is due to freshen. A longer dry period is not necessary for proper fitting. If the cow is not in fair flesh during the latter part of the lactation period, she should be fed a little more liberally than if she were not to be tested the next lactation. Then she can be gotten into the desired condition in a 60-day dry period.

During the dry period the same concentrate mixture, or so-called "fitting ration," may be used in fitting cows for official test that is fed to the other dry cows in the herd. (**1082**) The amount to be fed will depend entirely on the condition of the individual cow. It should not be necessary to feed more than about 12 lbs. of concentrates daily. Extremely heavy feeding during the dry period is not economical, and may result in the cow having a poor appetite at the start of the test period.

It is a good plan to feed during the dry period the same roughages that will be used when the cow is on test. A liberal amount of well-cured legume hay or of mixed hay rich in legumes should be fed, so there will be a plentiful supply of carotene and vitamin D. Corn or sorghum silage is also excellent at this time.

1104. Feed and care before and after calving.—When the cow is to be kept in a box stall during the test period, she should be put in it a few weeks in advance of calving, so she will become used to her surroundings. The cow should be in the proper condition for freshening about 2 weeks before calving, because it may be

necessary to reduce the concentrate allowance considerably to prevent extreme congestion of the udder.

Some congestion is normal with cows of high productive capacity that are well fitted. However, the udder must not be allowed to become caked and hard. If this occurs, the cow must be fed scantily for a time after she freshens. This will result in her using up her body reserve of fat very rapidly. Rubbing the udder twice daily with a mixture of one-half cod-liver oil and one-half ethyl alcohol will do much to prevent undue congestion and to keep the udder soft.

Many breeders discontinue feeding the regular fitting concentrate mixture 10 days to 2 weeks before calving and give instead a "cooling ration." However, no change in the mixture is necessary if the cow is not constipated. It is essential that her bowels be in a laxative condition before calving. A warm bran mash is an excellent mild laxative. If necessary, the cow should be given a dose of mineral oil or Epsom salts.

Those who prefer to use a special "cooling ration" before calving feed such a mixture as 2 parts wheat bran, 2 parts ground oats, and 1 part linseed meal. For a day or so before calving, some breeders even feed no concentrates except a bran mash, or a warm mash made of equal parts of bran and whole oats.

The care of a test cow at calving time is little different from that for any other cow. (1084) The danger from milk fever is greater, however, and preventive measures should be taken at the first signs of its appearance. The calf should be removed after it has had one feeding.

1105. Getting the test cow on feed.—The cow must be gotten on feed as quickly as possible, but extreme care must be used not to force her too fast. For several days after calving she should be fed the same "fitting ration" that has been used during the dry period. For the first 24 hours, only about 1 lb. of the mixture should be given at each feeding. This may be sprinkled over an allowance of soaked beet pulp.

The amount to be fed after this will depend on the condition of the udder and upon the cow's appetite. If the cow is doing well, 6 to 8 lbs. a day of the fitting ration may be fed during the second to the fifth day. On the other hand, if the udder is badly congested, but little of the fitting ration can be fed until the congestion is over.

After the fifth day, if the cow has a good appetite and her udder is in satisfactory condition, the allowance should be gradually increased by adding a small amount of the mixture which is to be fed throughout the lactation period (the so-called "test ration"). A good plan is to increase the amount at the rate of 0.1 lb. per feed until full feed is reached. When the cow is on full feed, the fitting ration is then gradually replaced by the test ration.

At the first sign of a dull appetite, no further increase should be made until the cow seems ready to handle more feed. Concentrates should never be left before a cow, hoping she will eat the rest. If she needs the feed, she will eat it at once. In case the cow does not show an eager appetite, most experienced herdsmen reduce the concentrates for one or two feeds to allow her to become hungry.

Only a good herdsman can decide when a cow is actually on full feed. The object should be always to feed no more concentrates than are needed for maximum production. Forced feeding is a foolish practice. By crowding them on rich feeds beyond the safety point in an attempt to secure a little higher production, many valuable animals have unfortunately been ruined. They have failed to breed afterwards, their udders have been spoiled, or their digestive systems have been injured.

The upper limit of concentrates should be about 25 lbs. per head daily, not including soaked beet pulp which is often fed in addition, as is mentioned later. It is best not to feed first-calf heifers more than 15 lbs. per head daily of the concentrate mixture.

1106. Necessity of liberal feeding.—When maximum yields are desired, cows on test must be fed greater amounts of nutrients than are recommended in the feeding standards. This was well shown in experiments by Woodward of the United States Department of Agriculture, who compared the records of cows on official test with their records made under the usual system of feeding and care for cows not on test.[61]

When on official test the cows were full fed on concentrates, with a large quantity of alfalfa hay, a small amount of silage, and soaked beet pulp in addition. They were milked 3 times a day, were kept in box stalls, and were bred to freshen about 15 months from the previous date of calving. Because of the liberality of feeding and the other conditions favorable for a maximum yield, the cows yielded approximately 50 per cent more milk than during other lactation periods when they were fed according to usual good dairy practice.

When not on test, the cows received

fully as great an amount of nutrients as advised in the feeding standards for the amount of milk they yielded. They were kept in stanchions, were milked twice a day, and were bred to freshen about 12 months from the date of previous calving.

In addition to showing the necessity of liberal feeding and the best of care when maximum records are desired, these experiments emphasize the difference between records of production under such test conditions and records under ordinary herd conditions.

1107. Rations for test cows.—The "test rations," or concentrate mixtures, used by various breeders for test cows differ widely, but nearly all have certain general characteristics. They are usually made up of a considerable variety of palatable feeds; they include a goodly proportion of such bulky feeds as wheat bran, ground oats, and dried beet pulp, and in addition a sufficient amount of protein-rich feeds, such as linseed meal, soybean oil meal, cottonseed meal, coconut oil meal, distillers corn dried grains, and gluten meal or gluten feed.

When the cows are fed a liberal amount of legume hay or of mixed hay high in legumes, it is advisable to use a concentrate mixture that contains about 16 to 18 per cent protein. If a mixture is used which is considerably higher in protein, a large excess of protein will be furnished, which will throw an increased load on the kidneys. When little or no legume hay is fed, the concentrate mixture should have 19 to 20 per cent protein.

In order to provide plenty of fat for maximum production, the concentrate mixture should contain at least 5 per cent of fat. **(1020)** Since certain feeds may have a slight effect in increasing the fat content of milk, it is a good plan to include one or more of these feeds in the test mixture. Such feeds are coconut oil meal, soybeans, and palm-kernel oil meal. **(1064)**

A concentrate mixture that has given excellent results when used with legume hay in the Cornell University herd is: 400 lbs. ground corn or hominy feed, 370 lbs. ground oats, 400 lbs. wheat bran, 300 lbs. distillers corn dried grains, 300 lbs. coconut oil meal (old process), 200 lbs. linseed meal, 10 lbs. salt, and 20 lbs. steamed bone meal. This mixture contains about 18.5 per cent protein.

A concentrate mixture with about 20 per cent protein, recommended by Bender of New Jersey is as follows: 600 lbs. ground corn or hominy feed, 400 lbs. ground oats, 300 lbs. wheat bran, 250 lbs. linseed meal, 150 lbs. corn gluten meal, 150 lbs. cottonseed meal, and 150 lbs. brewers' dried grains.[62] To each ton are added 20 lbs. ground limestone, 20 lbs. steamed bone meal, and 20 lbs. salt.

A mixture having 19 per cent protein, recommended by Nevens of the Illinois Station, is: 560 lbs. ground corn, 200 lbs. ground oats, 200 lbs. wheat bran, 200 lbs. dried beet pulp, 400 lbs. linseed meal, 200 lbs. corn gluten feed, 200 lbs. cottonseed meal, 20 lbs. steamed bone meal, and 20 lbs. salt.[63] The considerable difference in these formulas well shows that no one concentrate mixture is preferable to all others. In these mixtures ground barley or other grain may be substituted for part or all of the corn.

A test cow should be supplied with as much well-cured hay as she will eat, for this is the best insurance that she will receive a plentiful supply of carotene and vitamin D. Legume hay or mixed hay high in legumes is much preferable to grass hay. If the latter is used, it should be early-cut and of good green color. First-cutting alfalfa hay is satisfactory, if it is well cured, and may even be preferable to second-cutting or third-cutting hay, which is sometimes too laxative. Second-cutting mixed hay, high in clover or alfalfa, is excellent. If the cows are in box stalls, the hay may be kept before them at all times in racks. Before each new supply of hay is put in the racks, any waste should be removed.

Opinions differ concerning the feeding of silage to test cows. When silage is fed, the allowance should be limited to 20 or 25 lbs. per head daily. If test cows are provided all the silage they will eat, they will consume so much of this bulky feed that they will not be able to eat as much concentrates as needed for maximum production.

Many experienced feeders of test cows prefer to use soaked beet pulp as a succulent feed instead of silage. The allowance is usually about 5 or 6 lbs. of dried beet pulp per head daily for cows of the smaller breeds and up to 9 or 10 lbs. for Holsteins. Some years ago the feeding of sliced mangels or sugar beets to test cows was a common practice in the United States. Since soaked beet pulp has been found to give just as good results, it is now generally used instead of roots, as it is much more convenient and also cheaper.

In summer, test cows should, if possible, be turned out on good pasture each day, but they should not be kept on pasture so long that they will fail to eat the desired amount of concentrates. When they are started on pasture in spring, they should not be left on

the pasture more than an hour the first day, for too large an amount of the green feed will be unduly laxative. The feeding of hay should be continued throughout the pasture season, to avoid an over-laxative condition.

Test cows are generally fed concentrates as many times a day as they are milked. When soaked beet pulp is fed, it seems to make the concentrate mixture a trifle more palatable if it is mixed with the beet pulp.

1108. General pointers.—It is advisable to have cows freshen in the fall when they are to be tested, for their yield of milk will be appreciably greater than if they freshen at another period. Also, the percentage of fat for the year will be slightly higher. (**1061**)

For maximum records, Holstein cows are usually milked 4 times a day and other cows at least 3 times. (**1058**) Box stalls should be provided when maximum records are desired, for this slightly increases the yield. (**1088**)

When the weather is good, test cows should be turned out for exercise in winter for an hour to a half hour a day, depending on the temperature. This aids in keeping them healthy and in developing a keen appetite. Also, it keeps their legs in condition and prevents their hoofs from growing too long.

At all times the cows should have comfortable quarters and regular care and attention, always by the same herdsman, if possible. The stable should be kept free from flies during the summer. It must always be borne in mind that only when a test cow is comfortable, contented, and in the best of health will she respond with continued production of the maximum yield of which she is capable.

There is much difference of opinion as to whether or not the useful life of a dairy cow is shortened by feeding her all the concentrates she will consume, in an effort to secure maximum production. Without much question, many cows have been injured and their future usefulness even destroyed by injudicious crowding when on test. On the other hand, by following such methods as have previously been described, experienced herdsmen are usually able to feed cows so as to secure very high records of production without apparent injury.

QUESTIONS

1. State 10 essentials in the proper feeding and care of dairy cows.
2. Why is it important that the amount of concentrates for each cow be adjusted to her actual yield of milk and fat?
3. Discuss the importance of the following for dairy cows: (a) Palatability of feeds; (b) variety in the concentrate mixture; (c) bulkiness of the concentrate mixture; (d) rations that are slightly laxative; (e) an abundance of good roughage; good hay; (f) succulent feeds.
4. Why is good pasture necessary for low-cost milk production?
5. What are the best dairy pastures in your region?
6. Discuss: (a) Supplementing short pasture; (b) feeding concentrates to cows on pasture.
7. Why is it important that cows have a dry period?
8. How would you dry off a persistent producer?
9. Discuss the feeding of cows during the dry period.
10. What is the approximate gestation period for dairy cows?
11. Discuss the feed and care of a cow at calving time; after calving.
12. What is the cause of milk fever and the usual method of treatment?
13. Describe one method recommended for preventing milk fever.
14. What is the cause of ketosis? State two methods of treatment.
15. Discuss the requirements of dairy cows for shelter and comfort.
16. What are the advantages and disadvantages of the loose-housing method?
17. Discuss fly control on the dairy farm.
18. Why is exercise important for dairy cows?
19. Discuss the frequency and order of feeding dairy cows.
20. Discuss the importance of proper milking, explaining how cows "let down" and "hold up" their milk.
21. State 4 important rules for machine milking.
22. Discuss the various items of cost in producing milk, stating the 7 classifications into which the expenses are commonly grouped.
23. Estimate the approximate cost of producing milk in your locality according to a formula, and using local prices for feeds and for man labor.
24. Discuss the effect of season of year on cost of milk production.
25. State 7 important factors in reducing the cost of milk production.
26. In what respects do the feeding and care of cows on official test differ from the ordinary methods used for economical milk production?

CHAPTER XXVII

RAISING DAIRY CATTLE

I. Nutrients Required for Growth of Dairy Cattle

1109. Importance of proper raising of well-bred heifers.—It has been emphasized previously that to secure a good net income from dairying, the first necessity is a herd of high-producing cows. The most certain method of developing a high-yielding herd is by replacing the poor producers with well-bred, home-raised heifers of greater productive capacity.

Such heifers should be from the best cows in the herd; they should be sired by a purebred bull which has been selected for ability to transmit high production; and they must be so raised that they will have a large capacity for converting feed into milk. Even when well fed, many cows are unable to develop their full inherited capacity for milk production, because they were stunted during growth by a lack of feed or by nutritive deficiencies.

The dairyman who follows the plan of purchasing his replacements will often be badly disappointed, even if he is careful to buy only heifers or cows whose appearance is promising. The farmer from whom he buys will naturally desire to retain for his own herd the heifers out of his very best cows. In addition to the difficulty of buying animals that will prove profitable, there is also much more danger of introducing disease when replacements are purchased.

1110. Nutrient requirements.—Before discussing the various rations suitable for raising dairy cattle, we should have clearly in mind the nutrient requirements for growth, which have been considered in Chapter IX. In raising dairy cattle especial attention must be given to providing: (1) Plenty of protein; (2) protein of satisfactory quality; (3) enough total digestible nutrients to permit normal growth; (4) sufficient minerals, especially calcium, phosphorus, and common salt; and (5) liberal amounts of vitamins. These requirements are discussed in detail on the following pages.[1]

In the Morrison feeding standards, given in Appendix Table III, recommendations are made concerning the amounts of dry matter, digestible protein, total digestible nutrients, calcium, phosphorus and carotene that should be supplied young dairy cattle at various stages of growth. These recommendations are based on the results of the experiments that have been conducted, especially by American experiment stations, to determine the requirements for the normal development of young dairy cattle.

At birth, a calf is actually not a ruminant, for the rumen has developed but little. Its needs for protein of high quality and for B-complex vitamins are therefore similar to those of pigs or chicks. These requirements are amply met when the calf is fed a normal amount of milk for at least 6 to 9 weeks and is supplied with good roughage. By that time the rumen will have developed sufficiently so that the calf has become a real ruminant.[2] Then ample supplies of the B-complex vitamins are synthesized in the fermentations that take place in the rumen, and also the quality of protein is of much less importance, if ample good roughage is fed. (**209, 112**)

When calves are weaned at only a few days of age and are fed a milk replacer, instead of milk, high-quality protein and B-complex vitamins must be provided in the replacer. (**1142**) The rumen develops more rapidly in calves if they are supplied with plenty of suitable hay as soon as they will eat it.[3] In

some cases calves are ruminating at 2 to 3 weeks of age.

1111. Amount of protein required.—Like other young animals, calves need a relatively large proportion of protein in their rations to provide for the rapid growth of their protein tissues. The proportion of protein required becomes less as the animal grows older, because less of the gain then consists of protein. (259)

But little experimental information is available concerning the minimum amounts of protein needed by dairy calves up to the age of 4 months. Even for older animals the data are not very extensive. The recommendations in the Morrison standards are based on a study of the available information, including recent New York experiments and New Hampshire and English investigations.[4]

1112. Quality of protein.—The kind or quality of protein in the ration is undoubtedly important for very young calves, because the paunch, or rumen, has not yet developed much. (112) However, during this period calves usually receive sufficient milk to insure an ample supply of good-quality protein.

By the time a calf is 3 or 4 weeks of age, it is eating some hay and the rumen has developed enough for the bacterial action to occur, which is characteristic of digestion in ruminants. The quality of protein in the ration then becomes of much less importance, as has been pointed out in Chapter V.

When calves are fed a reasonable amount of whole milk or skimmilk until they are 4 or 5 months of age, no special attention need be paid to the quality of protein furnished by the rest of the ration. As is shown later, an excellent ration for calves after 3 to 4 weeks of age is merely skimmilk plus cereal grain and good legume hay.

When milk feeding is discontinued at 6 to 9 weeks of age, as in the "calf starter" method which is discussed later, the quality of protein in the calf starter is of importance until the calves are 3 or 4 months old. However, good results are secured with calf starters which contain no animal protein, but in which a considerable part of the protein is supplied by soybean oil meal, a feed that also furnishes protein of high quality. (1141)

If calves are weaned at only a few days of age and fed a milk replacer, the quality of protein is very important.[5] (1142)

1113. Total digestible nutrients.—Since the rumen of a young calf is not yet well developed, it must be fed chiefly on milk or on concentrates high in digestible nutrients and low in fiber. As the calf grows older, it can utilize more and more roughage; until after 10 months of age the ration may even consist entirely of roughage, if it is of excellent quality.

The amounts of total digestible nutrients advised in the revised Morrison feeding standards for young dairy cattle at various stages of growth are based on investigations conducted at several experiment stations, especially recent Vermont experiments and studies at the Minnesota, Missouri, and New Hampshire Stations.[6] It will be noted that the amount of total digestible nutrients required per head daily increases gradually from 1.8 to 2.2 lbs. at 100 lbs. live weight up to 10.0 to 12.0 lbs. at 1,000 lbs. live weight.

1114. Fat. — Recent experiments have proved that young calves need a certain amount of fat in their diet.[7] Calves fed a fat-free synthetic ration from a few days of age could not grow and finally died. They showed various symptoms of fat deficiency—rough hair coat, partial loss of hair, leg-weakness, muscular twitches, diarrhea, and emaciation. Only 1 to 2 per cent of a suitable fat prevented the trouble. The deficiency was not a lack of an essential fatty acid, for it was prevented by adding a hydrogenated fat, in which the unsaturated fats had all been changed to saturated fats. (133)

This need for fat is fully met when calves are fed whole milk for 6 to 9 weeks in the usual calf-starter method. However, it must be borne in mind in making up a milk replacer for very young calves, or when whole milk is replaced

by skimmilk or reconstituted skimmilk at too early an age.

1115. Minerals.—If growing dairy cattle are fed rations that are otherwise satisfactory, there will commonly be no deficiency of any mineral except *common salt.* As soon as calves begin to eat concentrates, salt should be provided where they can take what they wish. Under certain conditions there may also be a deficiency of *phosphorus* or of *calcium,* as is pointed out in the following article.

Iodine is furnished in ample amounts by the ordinary rations fed growing cattle in most districts. If any calves at birth show evidence of goiter, or "big neck," this should be prevented in the future by the use of iodized salt or some other iodine supplement, as shown in Chapter VI. (**170**) In an area where there is a deficiency of cobalt or one of the other trace minerals, the lack should be corrected as shown in Chapter VI. In other regions there is no benefit from using a trace-mineral supplement.[8]

If calves are raised too largely on milk, without much roughage, anemia may develop because of the deficiency of iron and copper.[9] (**174**) This may be prevented by providing the small amounts of these minerals needed.

1116. Calcium and phosphorus.—If calves are fed a normal amount of whole milk or skimmilk, they will receive an ample amount of both calcium and phosphorus. Calves and heifers will get an abundance of calcium when they are fed plenty of legume hay or mixed hay high in legumes. Even when they get only non-legume roughage, such as grass hay or grass pasturage, there will generally be no lack of calcium, unless the soil on which the forage is raised is unusually low in calcium.[10] If there is any possibility of a deficiency, calcium can be provided cheaply by ground limestone or some other calcium supplement. (**157**)

There will be no lack of phosphorus, after calves are weaned from milk, if they are fed 2 to 3 lbs. per head daily of a concentrate mixture containing 10 to 20 per cent of such phosphorus-rich protein supplements as wheat bran, wheat middlings, linseed meal, or cottonseed meal.

When growing cattle are fed only cereal grains and hay, with or without corn or sorghum silage, there may be a serious lack of phosphorus if the soil on which the roughage is grown is deficient in this mineral. In such cases bone meal or some other safe phosphorus supplement should be provided, as advised in Chapter VI. (**158**)

The amounts of calcium and phosphorus advised per head daily for young dairy cattle at various stages of growth are stated in Appendix Table III. These recommendations are based on recent investigations at the Vermont Station and on Massachusetts, Michigan, Oregon, and West Virginia studies.[11]

It will be noted, for example, that allowances of 13 grams of calcium and 12 grams of phosphorus are recommended per head daily for an 800-lb. growing animal. So long as sufficient calcium and phosphorus are provided, the proportion between the amounts of these minerals (the calcium-phosphorus ratio) can vary considerably for cattle, without producing any detrimental results. (**152**)

1117. Vitamin A or carotene requirements.—Dairy calves undoubtedly suffer more often from a lack of vitamin A than from a deficiency of any other vitamin. A serious lack of it will produce disaster even in animals 1 to 2 years old.[12] However, the vitamin A needs are readily met when calves are raised according to one of the methods described later in this chapter.

It has been pointed out previously that young animals are born with only a very small supply of vitamin A or carotene in their bodies. (**270**) They are therefore dependent chiefly on the amounts they receive in their food. Fortunately, the colostrum from properly fed cows is very much higher than normal milk in vitamin A value. Indeed, it may have 100 times as much as normal milk. The high vitamin A value of colostrum is one of the chief reasons why it is so important for calves to receive a normal amount of it after birth and for the first 3 days.

Because normal whole milk from well-fed cows is rich in vitamin A value, there will commonly be no lack of vitamin A during the period when a calf is fed the usual amount of whole milk. However, in order to insure plenty of vitamin A and also to furnish other vitamins, it is important, as is emphasized later, to supply excellent legume or mixed hay just as soon as the calf will eat any of it. (1133)

HIGH-QUALITY HAY IMPORTANT FOR CALVES

To insure a plentiful supply of vitamins, it is essential that calves have excellent legume or mixed hay as soon as they will eat it. A "calf starter" is also being fed this calf in the feed box. (From New York State College of Agriculture, Cornell University.)

Though skimmilk is very low in vitamin A value, there is usually no deficiency of vitamin A when calves are changed entirely from whole milk to skimmilk by 3 or 4 weeks of age, if care is taken to let them have plenty of first-rate hay. If whole milk is discontinued even earlier, or if the hay is not of good quality, it is important to feed a vitamin A supplement, such as cod-liver oil concentrate, or to use a calf starter or a milk replacer that is reinforced with such a vitamin supplement.[13] New Mexico experiments show, however, that if calves are fed plenty of good-quality legume hay, there is no benefit from supplying a vitamin A supplement when the feeding of whole milk is discontinued at 30 days of age.[14]

If a cow is milked a few days before calving (prepartum milking) in an attempt to reduce congestion of the udder, the colostrum will be secreted mostly before she calves.[15] (1084) Unless the calf can be fed colostrum from another cow or stored colostrum, a vitamin supplement should be added to the milk.

Calves can use vitamin A much more efficiently than they can carotene, especially at an early age. In Connecticut studies it required 5 or more times as much carotene as of vitamin A to prevent symptoms of vitamin A deficiency.[16] However, providing plenty of carotene-rich hay as soon as they will eat it will meet their needs. Since feeds of plant origin supply carotene and not vitamin A, the vitamin A requirements of cattle are commonly stated in terms of carotene.

A special committee of the National

Research Council has recommended in its report on *Recommended Nutrient Allowances for Dairy Cattle* that growing dairy cattle receive 4 milligrams of carotene (beta-carotene) daily per 100 lbs. live weight.[17] To insure an adequate supply under all conditions, the amount was placed fully twice as high as the minimum that has been shown to be necessary to prevent symptoms of vitamin A deficiency under controlled experimental conditions.[18]

Considerably more carotene is needed in winter than in summer, and the difference does not seem to be due chiefly to the temperature.[19] Guernseys and Jerseys require slightly more carotene per 100 lbs. live weight than do Holsteins or Ayrshires.

To secure thrifty calves that start out life with a normal, though limited, supply of vitamin A, it is very important that the cows receive plenty of vitamin A value during pregnancy. As has been emphasized previously, the results are disastrous when cows are fed for long periods on rations seriously deficient in vitamin A. (**564, 1042**) Not only are the calves often born dead or very weak, but also the milk is so deficient in vitamin A that even calves from well-fed cows cannot be raised on it without a vitamin A supplement.

Feeding a cow during pregnancy a ration having plenty of carotene considerably increases the vitamin A content of the colostrum and later milk. It also insures a normal supply of vitamin A in the body of the calf at birth. As shown previously, the store of vitamin A in the calf at birth and the amount of the vitamin in the colostrum can be increased still more by feeding a concentrated vitamin A supplement to the cow for some weeks previous to calving. (**270**)

1118. Vitamin D requirements.—Calves must have an ample supply of vitamin D, for a lack will cause serious trouble from rickets.[20] The symptoms of this nutritional disease have been described previously. (**153**) However, there will ordinarily be no lack of vitamin D if care is taken to provide good-quality field-cured legume or mixed hay as soon as the calves will eat it. Since whole milk is not rich in this vitamin, even a liberal amount of it may not furnish enough to protect calves against rickets. Fortunately, calves will begin to eat hay at 2 or 3 weeks of age, and if then supplied with good hay, they will soon eat sufficient to furnish the needed amount of the vitamin.

In Michigan experiments even 1 lb. of field-cured U.S. No. 1 alfalfa hay or 2 lbs. of No. 2 timothy hay per head daily provided enough vitamin D to prevent rickets in calves, when it was the only source of the vitamin.[21] In Vermont experiments that have been mentioned previously, calves and heifers fed poor-quality, late-cut timothy hay as the only hay and not on pasture in summer showed no evidences of a vitamin D deficiency. (**1047**) Adding a vitamin A and D supplement to the ration with this poor hay increased the gains, but was of little benefit for other animals fed good hay.

Since sunlight that has not passed through ordinary window glass has an anti-rachitic effect, exposure of calves to sufficient direct sunlight prevents rickets. (**201**) Winter sunlight in the northern states has much less anti-rachitic effect than summer sunlight, and also young dairy calves are not generally turned outdoors at all in cold weather. However, if calves are supplied with plenty of good-quality sun-cured hay, they usually receive enough vitamin D, even if in the stable all the time and exposed only to sunlight that has passed through window glass.[22] In experiments by the United States Department of Agriculture, even barn-dried hay or wilted hay-crop silage prevented rickets in dairy calves not exposed to any sunlight. (**204**)

If a very liberal amount of concentrates is fed to calves, especially to those also getting milk, they may fail to eat enough hay to prevent rickets.[23] Also, sometimes calves that are making excellent growth develop mild cases of rickets, showing particularly the characteristic sag in the back, just behind the shoulders. Such animals are growing rap-

idly in skeleton, and therefore need especially liberal amounts of vitamin D.

To guard against a possible vitamin D deficiency, it is a good plan to include a suitable amount of a vitamin D supplement in calf starters used in the calf-starter method of raising calves, and also in milk replacers. (1141, 1142)

The special committee of the National Research Council in the report on Recommended Nutrient Allowances for Dairy Cattle, which has been mentioned previously, recommends an allowance of 400 International Units of vitamin D per 100 lbs. live weight for dairy calves.[17] This allowance evidently provides a considerable margin of safety, for experiments by the United States Department of Agriculture indicate that the minimum requirement of young dairy calves for vitamin D in the form of alfalfa hay is only 150 to 200 International Units per 100 lbs. live weight.[24]

1119. Other vitamins.—Generally, there is no deficiency of B-complex vitamins when dairy calves are raised by one of the usual methods. As soon as the paunch, or rumen, becomes sufficiently developed for normal ruminant digestion to occur, the B-complex vitamins are synthesized in the rumen by bacterial action.[25] (209) Before this, these vitamins are supplied by the milk the calf is generally fed.

If calves are weaned from milk at only a few days of age, B-complex vitamin supplements should be included in the milk replacer, if it does not contain a considerable proportion of dried skimmilk and other dairy by-products. (1142)

In most experiments there has been no benefit from adding to a normal ration for dairy calves, either B-complex vitamins or yeast, which is rich in these vitamins.[26] Ordinarily, a deficiency of B-complex vitamins can be produced only when calves are raised on an abnormal synthetic ration that includes no ordinary roughage.[27] In experiments in which calves have been fed such rations, it has been proved that they require thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, biotin, and vitamin B_{12}.[28] All these vitamins are provided amply in the ordinary methods of raising dairy calves.

Under usual conditions ascorbic acid, vitamin C, is of no importance in raising dairy cattle. (224) Synthesis of this vitamin in the body begins by the time a calf is 2 or 3 weeks old, and there is generally a sufficient store in the body at birth to meet the needs up to this time. Calves have been raised successfully on a ration so lacking in ascorbic acid that it would produce scurvy in guinea pigs within a month.[29]

If calves are fed the usual rations, with plenty of good roughage, there is no lack of vitamin E. (1040)

1120. Vitamin pills or capsules.—It has been advocated that, in herds where the losses from scours or other diseases have been serious, the calves be given soon after birth and during the first few weeks vitamin pills or capsules which supply vitamin A, vitamin D, niacin, and in some cases other B-complex vitamins.[30] However, in extensive experiments in several states and with great numbers of calves, the use of such vitamin pills or capsules has not been beneficial.[31] They have not lessened scours or other diseases, or improved the appearance or condition of the calves.

It has been pointed out earlier in this chapter that when the feeding of whole milk is discontinued at an extremely early age, it is important to feed a vitamin A supplement. (1117) Also, under certain conditions, the use of a vitamin D supplement is advisable. However, there is generally no need of using such vitamin supplements when calves are fed the usual amount of whole milk and supplied with good-quality hay at an early age.[32]

1121. Antibiotic feed supplements.—Since the discovery was made that the feeding of certain antibiotics increased the growth of some young animals, scores of experiments have been conducted by the experiment stations to determine the effects of antibiotic feed supplements on dairy calves.[33] (966) Most of these investigations have been with aureomycin

feed supplements or with pure aureomycin (chlortetracycline).

In the great majority of the experiments, but not all, the addition of an aureomycin supplement to the ration has increased the rate of gain of dairy calves decidedly. It has generally reduced the cases of scours and other infectious diseases, and improved the thriftiness and the appearance of the calves. These effects are greater in herds where there has been much trouble from disease. However, an antibiotic supplement is no cure-all, and it does not give protection against unsanitary and slovenly practices.

The effect of the antibiotic supplement is the greatest during the first 7 weeks of life, and there is little effect after calves are 6 months old. After this age, heifers that have not received an antibiotic supplement previously will probably tend to grow faster than those which have had the supplement, and by the time they freshen there will likely be no appreciable difference in size. Therefore, in raising replacement dairy heifers the chief advantage from feeding an antibiotic supplement when they are calves is the lessening of scours and other diseases.

An antibiotic supplement has the most effect when it is added to the milk or milk replacer during the first few weeks. If this is not done, there may be a slight benefit from including an antibiotic supplement in the calf starter.

Aureomycin and terramycin feed supplements generally stimulate the appetite so that calves eat more feed. In some experiments less feed has been required per 100 lbs. gain with the antibiotic, but in a greater number of trials the feed efficiency has not been increased. The use of an antibiotic supplement does not apparently increase the digestibility of the ration in most cases.

In some experiments terramycin has been as effective as aureomycin, but not in others. Bacitracin has not equalled aureomycin in effectiveness, and penicillin, and chloromycetin have been ineffective. The results with streptomycin have differed greatly. Feeding 30 milligrams of aureomycin or terramycin per calf daily has generally been as beneficial as a higher level.

1122. Surfactants; arsonic supplements.—Only a few experiments have been reported thus far in which a *surfactant,* or surface-active agent, has been used to supplement a ration for young calves.[34] (967) Except in one test, a surfactant has been less effective than aureomycin in increasing growth and preventing scours, or it has not been beneficial at all.

The data are yet too limited to show whether *arsonic supplements* (arsanilic acid or other arsonic acid derivatives) are as effective as an antibiotic for young calves.[35]

1123. Cud inoculation.—When a calf is only a few days of age, its rumen is developed but little, and the characteristic cellulose-digesting bacteria found in the rumen of older cattle are not present in appreciable amounts. If the calf is in contact with older cattle, the rumen soon becomes inoculated with these organisms, perhaps by eating feed which has been slobbered on by these animals while chewing the cud.

Pounden and Hibbs of the Ohio Station believe, as a result of their studies, that when calves are separated from their dams shortly after birth and kept in individual pens, it is desirable to inoculate them by placing in the back of the mouth fresh cud material from healthy older cattle.[36] They advise giving the treatment once a week for the first few weeks. The cud material can be secured from the mouth of a ruminating cow. In their tests the health of calves thus inoculated was improved. Frozen or dried rumen contents or dry commercial preparations were not a satisfactory substitute for the fresh cud material.[37]

In trials at other experiment stations there has been no benefit or only very slight benefit from inoculating calves with fresh cud material.[38]

1124. Water.—Calves over 8 weeks of age should have plenty of fresh water at least twice a day, even when they are fed normal amounts of milk. A lack of water may seriously reduce the rate of

growth.[39] Up to 8 weeks of age, calves will drink but little water if they have a liberal amount of milk, and there is then probably little advantage from supplying water in addition during this period.

After this, they will drink rapidly increasing amounts of water, and should be furnished it. It is especially important to provide plenty of water when calves are raised on a minimum amount of milk or on dry calf starters.

For a young calf it is probably best to give it lukewarm water twice a day, a couple of hours after it is fed milk, instead of having a drinking cup in the pen. With a drinking cup, the calf may go to it after the milk is finished and drink so much water as to cause scours.

In Idaho trials, calves fed 12 to 16 lbs. of skimmilk a day to 6 months of age drank the following amounts of water per day: At 4 weeks of age, 0.07 lb;. 6 weeks, 0.5 lb.; 8 weeks, 2.2 lbs.; 10 weeks, 4.3 lbs.; 12 weeks, 6.6 lbs.; 16 weeks, 12.9 lbs.; 20 weeks, 18.0 lbs.; and 26 weeks, 33.4 lbs.[40] In a Wisconsin trial calves raised on a dry calf starter and hay, with only 400 lbs. of whole milk the first few weeks, drank about 4,900 lbs. of water per calf up to 6 months of age.[39]

II. Raising Dairy Calves

1125. Precautions in raising calves.—Probably about 20 per cent of the calves born in our chief dairy districts die from disease, especially calf scours and pneumonia. To reduce these losses and raise vigorous, thrifty calves, careful attention to the following points is necessary:

As has been emphasized in the previous chapter it is important first that the cows be properly fed prior to calving, so that the calves are thrifty at the outset and so that the colostrum and later milk have a high vitamin content.

The cows should calve in a well-cleaned and disinfected maternity stall. To prevent the spread of disease, each calf should be kept in a separate calf pen for the first several weeks. The pen should be kept clean and well bedded, and should be thoroughly disinfected before a new calf is put in it. The walls between the pens should preferably be solid so there can be no contact of the calves.

The calves should be fed at regular intervals, and any change in the feed should be made gradually. Water and salt should be supplied. In summer, shade should be provided for calves on pasture. The feeder should watch for any signs of scours and at once take suitable measures to overcome the trouble.

White scours, or virulent scours, which usually occurs within 72 hours after birth, causes severe losses in some herds. This is a virus disease, which is readily transmitted by exposure of new-born calves to infected calves or contaminated pens.[41] A preventive, recently developed by Link of the Wisconsin Station, seems to be effective in herds where the trouble has been serious.[42] This product, which is now made commercially, contains dried irradiated blood serum, vitamin K, and predigested milk solids.

1126. Housing.—The quarters for calves should be well ventilated and lighted and drafts must be avoided. Where trouble from disease has been serious in large herds, it is a good plan to use small calf barns with only a few individual pens, instead of a large calf barn. Sometimes elevated floors, made of wire screen, are used in the individual pens to keep the calves drier and cleaner.[43]

In the southern states a method of housing young calves in small individual pens with no floors, placed on pasture, helps prevent disease and infection with parasites. One-half of the pen is roofed and in cold weather is enclosed on three sides. The pens are moved once a week to fresh spots of pasture. In Alabama tests excellent results have been secured by this method.[44]

Even in the northern states calves can be successfully raised in open sheds, if they are kept dry with plenty of bedding and are protected from drafts.[45] More feed will be required than in warmer quarters, but there is apt to be less trouble from disease.

1127. The new-born calf.—The care of the cow at calving time and the care of the new-born calf have been considered in the preceding chapter. (1084) A new-born calf is very sensitive to the treatment it receives and has but little resistance to certain diseases. Great care is therefore necessary to prevent infections, as has been emphasized in the previous discussion. The calf should always be protected from drafts and from cold and dampness, and the navel should be disinfected with tincture of iodine soon after birth.

If the cow's udder is soiled, it should be washed with soap and water and dried with a clean cloth before the calf nurses. The calf should nurse within an hour after birth, and if it is weak and fails to nurse, it should be helped patiently to get its first meal.

It is very important that the calf get the colostrum, or first milk, immediately after birth. (270) This protects the new-born calf against diseases, especially of the digestive system. Also, its very high vitamin A content is of great importance, for the calf is born with a very small store of the vitamin.

If for any reason a calf cannot receive colostrum milk, a vitamin A supplement should be administered and a colostrum substitute should be used, such as are now available. For this purpose an egg-white emulsion may be used, prepared by mixing the whites of 6 eggs with fresh cow's milk for the first feeding.[46] For the following feedings, one less egg is used each time.

1128. Utilizing surplus colostrum.—A good dairy cow generally produces much more colostrum than her own calf can consume. The surplus is often wasted on dairy farms. Experiments have proved that the gains of calves are increased when colostrum feeding is continued for a longer period than normal, by giving a calf other colostrum than from its dam.[47] When surplus colostrum is available, it can replace part of the milk for any of the calves without causing scours.

Surplus colostrum may be stored for considerable periods by freezing it, which can often be done easily outdoors in winter in the northern states.

1129. Starting the calf on whole milk.—No matter what method of feeding is followed later, a calf should receive whole milk in normal amounts for at least 2 weeks, and preferably for 3 or 4 weeks or more if it is especially valuable or if it is not strong. For very young calves there is no satisfactory substitute for milk.

Hunger is a great aid in teaching a calf to drink, and therefore the first lesson had better be postponed until 10 to 12 hours after it is separated from its dam. One should be patient with the calf and remember that its instinct is to seek its food at a level above its nose and not down in a pail, and also that it frequently bunts the udder of its dam while nursing, thus massaging it. The calf can not be blamed if it follows these instincts for a time.

After putting a quart of fresh, warm milk in a clean pail, one is ready for the first lesson. A common method is to back the calf into a corner and stand astride it to hold it fast. Then hold the pail in one hand, dip the fingers of the other hand in the milk, and while the calf is sucking the fingers, bring its nose down into the milk. Then gradually withdraw the fingers, holding them at the end of the nose for a little while. Above all, be patient in repeating the process as needed. The calf pails in which milk is fed must be kept scrupulously clean and should be sterilized, if possible.

The young calf should be fed sparingly, for there is much more danger of overfeeding the first few days than of underfeeding. For the first day or two 5 or 6 lbs. of milk daily is a safe allowance for an average calf, with 8 lbs. as a maximum for a large, lusty one. This allowance should be divided between 2 or 3 feedings and the amount of each should be measured or weighed and not estimated. The milk should be fed as fresh as possible and at a temperature of 90° to 100° F., determined by a thermometer, instead of guessing at it. Feeding 3 times a day is slightly better for the calf during the first week or so and is advisable if the cows are milked thrice daily.

If possible, it is a good plan to feed the calf milk from its dam for the first few days, unless the milk is very high in fat. In this case it may be wise to use milk from a low-testing cow for a week or two, or else to add warm skimmilk or water to lower the fat percentage.

The allowance of milk should be gradually increased as the calf grows older, if it is thriving. Overfeeding, the cause of much trouble in calf rearing, should be avoided at all times. A safe plan is to keep the calf a little hungry. A good rule is to feed 1 lb. of whole milk daily per 10 lbs. live weight. Weak or sickly calves should be fed less, and even a large and vigorous calf should not be fed more than 12 lbs. a day. In case of indigestion or scours, the allowance should immediately be cut in half until the calf recovers.

Calves not in individual pens should be confined in stanchions for a time after the milk is drunk, until they consume their concentrate allowance and overcome the desire to suck each other's ears or udders. If this is not done, the shape of the udder may be injured or a heifer may later persist in sucking herself or other cows.

In some experiments calves have been less apt to suffer from digestive upsets when fed milk by means of "nipple pails" than when it is fed in ordinary pails.[48] In other trials there has been little difference in the results with nipple pails and other pails.[49] The calf gets milk more slowly from the nipple pail by sucking on the nipple, and cannot gulp the milk down, as from an ordinary pail. The advantages of nipple pails are offset more or less by the fact that more care may be necessary in cleaning them, to keep them in sanitary condition.

1130. Various methods of raising calves.—If one wishes to raise dairy calves so they will make maximum growth, regardless of expense, there is no better way than to continue the feeding of a considerable amount of whole milk for 5 or 6 months or longer. On account of the expense, however, relatively few dairy calves are raised on whole milk, except when they are reared by the "nurse-cow method." (1139) After calves have a good start on whole milk, they may be raised successfully by the several different methods described in detail in this chapter.

1131. Feeding grain and other concentrates.—When a calf is 1 to 2 weeks old, it should be taught to eat concentrates. Though certain mixtures are especially popular for feeding young calves, almost any mixture of the farm grains is satisfactory, or even a single grain. If the calf gets plenty of whole milk, skimmilk, or buttermilk, it will receive sufficient protein in the milk. Adding a small amount of such a feed as wheat bran or linseed meal to grain will usually make the mixture more palatable to calves, and therefore may be advisable, merely from this standpoint.

Such mixtures as the following are excellent for calves fed milk:

(1) Corn, 30 to 40 lbs.; oats, 30 lbs.; wheat bran, 10 to 20 lbs.; linseed meal, 10 lbs.

(2) Equal weights of corn or barley and of oats or wheat bran.

(3) Corn, 30 lbs.; wheat bran, 10 lbs.

(4) Corn, 30 lbs.; linseed meal, 5 lbs.

(5) Corn, 40 lbs.; wheat bran, 10 lbs.; linseed meal or soybean oil meal, 10 lbs.

In these mixtures other grains, such as ground barley, ground wheat, or ground grain sorghum, may be substituted for the corn and oats. Rye is less palatable and should not form too large a part of a mixture for calves. Dried beet pulp may be used as a substitute for part of the grain for calves 2 to 3 months old or more.

A limited amount of cane molasses can be used in place of grain for calves, but too large a proportion is apt to cause scours. In Louisiana trials the results were satisfactory when only 1 to 2 ounces of molasses per head daily were mixed with the concentrates at the start, and the amount of molasses increased very gradually until molasses formed one-half the concentrates when the calves were 5 months old.[50]

Other protein supplements may be used in place of linseed meal, soybean oil meal, or wheat bran in these mixtures. Standard wheat middlings or flour wheat middlings are good substitutes for wheat bran. Red dog flour is often used in mixtures for calves raised on a minimum of milk, because of its high digestibility.

Corn gluten feed, corn gluten meal, and peanut oil meal are satisfactory protein-rich supplements. Cottonseed meal may be used in the limited amounts stated previously. (813)

plenty of milk or skimmilk. In Wisconsin trials calves fed ground corn as the only concentrate with skimmilk and legume hay were thrifty and made good gains.[51] Others fed a mixture of corn, oats, wheat-bran, and linseed meal gained a trifle more, but the feed cost was higher.

Calves chew corn or oats thoroughly up to an age of 6 to 9 months and, after they have learned to eat concentrates, show a preference for the whole grain. Therefore, the whole grain gives as good or better results than when ground.[52]

Calves Need a Liberal Amount of Concentrates

To produce rapid and thrifty growth, calves must have a liberal amount of concentrates. The percentage of protein needed in the concentrate mixture will depend on whether or not they are receiving considerable whole milk or skimmilk.

These mixtures all provide sufficient protein for calves raised on plenty of milk (whole milk, skimmilk, or buttermilk). If the amount of milk is limited and especially if calves are weaned at an early age and raised on concentrates and hay alone, the mixture must contain much more protein. Also, a larger proportion of protein supplements is required when calves are raised on whey. Suitable mixtures to use under these various methods of feeding are stated later in the discussions of these methods.

Whole or ground oats are often used as the only concentrate for calves fed

When such a mixture as corn and linseed meal is fed, the corn is often ground to prevent the linseed meal from separating out. After calves are 6 to 9 months old, they chew grain less thoroughly, and corn and oats should then be ground. Such hard grains as barley, wheat, and the grain sorghums should always be ground. Coarse grinding is preferable to fine grinding for calves.

1132. Feeding concentrates.—The calf can be taught to eat the grain mixture by putting a handful or less in the bottom of the pail after it has finished drinking its milk. Some add the mixture

to the milk, but this is inadvisable, as the meal is then chewed less thoroughly. The calf that is backward may be taught to eat the mixture by rubbing some on its muzzle when it is through drinking milk, or by putting a little in its mouth. After the calf has learned to eat grain, the mixture should be fed dry in a suitable feed box or in the manger.

Until the calf is 2 to 3 months old, it may eat as much of the mixture as it desires, a supply being kept before it in a feed box. Care should be taken to clean the box out regularly.

Older calves fed a liberal allowance of skimmilk may be allowed up to 4 lbs. of the grain mixture a day, and those raised on calf meal, up to 5 lbs. a day. If the calves begin to eat more than this, the proper amount should be hand-fed twice daily, instead of letting them have all they will eat. Otherwise, they will not eat enough hay, and also the feed cost will be too high.

1133. Importance of plenty of good hay for calves.—It is very important that calves have hay of first-rate quality as soon as they will eat it. Green-colored, sun-cured hay is not only high in vitamin A value, but it is also the richest source of vitamin D among common feeds. In addition, it has a good content of B-complex vitamins. Supplying plenty of such hay will therefore prevent any deficiency of vitamins.

Providing ample high-quality hay also develops the calf's rumen more rapidly and hastens the establishment of mature-type cellulose-digesting bacteria.[53] In addition, it prevents anemia, which may occur in calves fed too largely on milk or milk and concentrates.[54]

At about 2 weeks of age, a handful of the hay should be placed each day where the calf can get it. Little will be eaten at first, but even this may be important in preventing rickets and other troubles. As the calf grows and its rumen develops, more hay will be eaten, until at 6 months of age it should be eating 3 to 5 lbs. a day. The amount of hay eaten per 100 lbs. live weight usually increases up to about a year of age.

The best way to feed hay to calves is in a slatted rack. All uneaten hay should be removed daily and fed to other stock, for calves do not like hay which has been picked over.

It is never safe to attempt to raise calves without plenty of good hay or other good roughage. As has been shown earlier, attempts to raise calves on milk alone or on milk and grain without roughage have ended in failure. (253)

Occasionally, a calf will show an abnormal appetite and will eat the bedding or will gorge on an undue amount of hay, which may result in a serious digestive disturbance. Fortunately, this rarely happens with healthy calves. Some breeders keep muzzles at hand and if a calf shows such a tendency, they muzzle it for the first month, except at the time it is fed milk and concentrates. The use of muzzles on all calves for the first month has been advocated as a protection against such trouble, but on account of the nutritive benefits that young calves secure from good hay, this practice seems unwise, except perhaps where there have been severe losses from calf diseases.

1134. Legume hay excels for calves.—Fine-stemmed, leafy legume hay is the best for calves, because of its high content of protein, calcium, and vitamins. Excellent quality mixed legume-and-grass hay that is high in proportion of legumes ranks next.

Occasionally, young calves may eat so much of excellent legume hay that its laxative effect may cause them to scour. This can be avoided by limiting the amount of hay or by starting them on mixed legume-and-grass hay. In experiments during 6 years by the author and associates at the Wisconsin Station, calves were allowed access to red clover hay from the start with uniform success, and in later trials were fed alfalfa with like good results.[55] In New York trials, calves fed U.S. No. 1 alfalfa hay ate more hay and made slightly more rapid growth than others fed mixed hay of similar quality.[56] Probably many cases of scours have been attributed to the laxative effect of legume hay when some other factor has really been responsible.

In general, the leafier that hay is,

the higher will be its value for calves. Second-cutting clover or alfalfa hay is therefore preferred to first-cutting. Good-quality lespedeza hay, soybean hay, cowpea hay, or mixed hay high in legumes are all very satisfactory for calves.

If no good legume or mixed hay is available for the calves, early-cut, well-cured grass hay can be used satisfactorily. In Oklahoma experiments calves raised by the calf-starter method with good prairie hay as the roughage made normal gains, although somewhat less than on alfalfa.[57] In a New York trial calves fed U.S. No. 1 timothy hay ate less hay and consumed more concentrates than others fed alfalfa, but even then grew less rapidly.[56]

That good growth can be secured on a very small amount of concentrates when heifers have plenty of first-class legume hay is shown by recent trials of the United States Department of Agriculture.[58] Heifers fed all they would eat of excellent alfalfa hay, made normal growth to 2 years of age when raised by the calf-starter method, with no milk after they were 60 days old and no concentrates at all after 8 to 9 months of age. The heifers received a total of only about 560 lbs. of concentrates per head, which is far less than is fed by most dairymen.

The importance of good hay is further shown by extensive Vermont experiments in which good grass hay was compared with hay from similar fields cut a month later.[59] When a year of age, heifers fed the late-cut hay averaged 60 lbs. less in weight than those fed the good hay. During the second year they still gained less rapidly, although both groups were fed some silage or green forage in addition to hay and concentrates.

If poor hay, low in carotene, must be used as the only roughage for calves and heifers, it is important to add a vitamin A supplement. Otherwise, a serious deficiency may result.[60]

In an area where but little legume hay is grown, alfalfa meal or alfalfa pellets make a satisfactory, though expensive, substitute for farm-raised hay. A suitable amount of the alfalfa meal or pellets may be mixed with the concentrates, and no other roughage fed.[61] When dehydrated alfalfa pellets are fed separately, calves may eat more pellets than they would of good alfalfa hay and will then gain correspondingly more.[62]

1135. Silage; roots.—After calves are 6 to 8 weeks old, they may be fed a small amount of good corn or sorghum silage, in addition to plenty of hay, but many dairymen prefer not to feed silage until the calves are 4 to 6 months old. The use of silage is not necessary in raising good calves, and feeding silage too early may cause more trouble from scours.

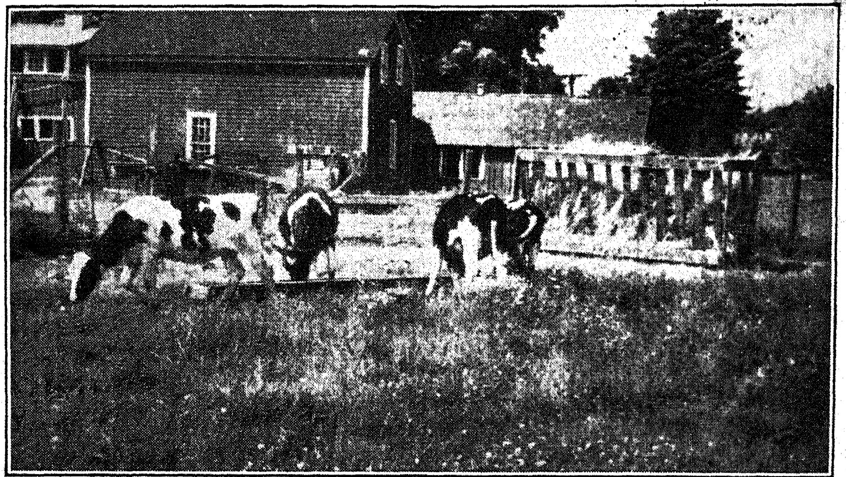
Corn or sorghum silage may be an economical addition to the rations of older calves and of heifers in the corn belt and in the sorghum-growing districts. However, such silage does not have the special nutritive values for calves which are possessed by good legume hay. This is because the silage is not rich in protein or in calcium, and it may have but little vitamin D. Hay-crop silage is a satisfactory substitute for part of the hay, especially for older calves and for heifers.

The results of experiments have differed widely in which hay-crop silage has been used as an entire substitute for hay in raising calves and heifers. In a trial by the United States Department of Agriculture, heifers were raised by the calf-starter method with a maximum of only 3 lbs. of concentrates a day and none after they were 8 months old.[58] Heifers fed wilted alfalfa silage as the only roughage or with a very small amount of hay did not eat anywhere near as much dry matter in roughage as others fed alfalfa hay, and did not make normal gains. After they were a year old, they made nearly as large gains as those fed alfalfa hay. It seemed that to produce equal gains with alfalfa silage it would be necessary to feed considerably more concentrates the first year than with alfalfa hay as the roughage.

Differing from these results, in New Hampshire trials yearling heifers made greater gains on hay-crop silage as the only feed than others made on hay, even

though they consumed less dry matter.[63] Also, in a Pennsylvania trial calves fed legume-grass silage as the only roughage made nearly as rapid gains as others fed hay, even when fed only a small amount of calf starter.[64] In Nevada and South Dakota tests heifers made only slightly less gain on alfalfa silage as the only roughage than others fed alfalfa hay, but in a Rhode Island trial hay-crop silage produced appreciably less gain than did corn silage.[65]

Where internal parasites are less serious, thrifty calves do well on clean pasture after they are 2 to 4 months old, if accustomed to it gradually and if they are fed plenty of other feed and are supplied with shade, shelter, salt, and fresh water. The scrawny, pot-bellied calves one often sees on pasture are usually not a result of the pasturage, but of the lack of milk and grain and of proper daily attention. In Georgia trials calves raised by the calf-starter method did well when



CALVES DO WELL ON PASTURE IF PROPERLY FED

Calves thrive on good pasture after they are 2 to 3 months old, if they are accustomed to it gradually and if they have plenty of other feed, as well as shelter, salt, and fresh water. A concentrate mixture is fed these heifers in a trough, and hay in a rack. (From New York State College of Agriculture, Cornell University.)

placed on fresh, clean pasture at only 7 days of age, with no hay at all.[67]

Roots are a satisfactory succulent feed for calves, but in the United States are much more expensive than silage.

1136. Pasture.—Pasture that is free from contamination with parasites is excellent for calves old enough to make good use of it. A pasture that has been grazed by cattle within a year or one that has been top-dressed with cattle manure should not be used for calves, as they are much more severely affected by internal parasites than are older cattle.

In the southern states the parasite problem is more serious than in the North, and North Carolina investigators advise that calves should not go to pasture until 10 months of age.[66] (1126)

If calves much under a year of age are pastured with older cattle, they may become badly infected with internal parasites from older cattle.

If calves are pastured when too young, there is more trouble from scours, and they may suffer from heat and flies. Many dairymen therefore prefer not to turn calves on pasture until they are 5 or 6 months old. Instead, the calves are kept in the stable, where they are more sure to receive proper feed and attention.

It has been pointed out previously in this chapter that direct sunlight is an effective aid in preventing or curing

rickets. During warm weather it is therefore well to let calves over 2 months of age have access to clean outside pens, if they are not on pasture.

1137. Raising calves on skimmilk.—Whenever skimmilk is available, the calves should be changed from whole milk to this by-product as soon as they have a good start. Calves raised on skimmilk may not make quite as rapid gains the first few months as when they are continued on a liberal allowance of whole milk. However, they will be just as large by the time they are 18 months to 2 years old and they will develop into just as productive cows.[68]

Skimmilk should be fed, if possible, fresh and warm from the farm separator. If the milk is not warm, it should be heated to 90° to 100° F. before feeding. Contrary to common opinion, it is not injurious to feed calves the foam which normally collects on separated milk, provided the proper amount of milk is fed. After the calf is 2 to 4 months old, it can usually be accustomed to cool milk, if the temperature is reasonably uniform. In a South Dakota trial, calves were successfully fed cold skimmilk from the start by means of nipple pails.[69] Sour skimmilk can be fed to calves 2 months old, if it is of good quality and if it is uniformly fed sour, and not sweet at one feeding and sour at another.

In raising calves on skimmilk, the change from whole milk to skimmilk may begin when the calf is 2 to 4 weeks old, the exact age depending on the vigor of the calf. The change should be made at the rate of about 1 lb. a day over a period of 7 to 10 days. In the case of very valuable calves, some whole milk is often fed for 2 months or longer. At the other extreme, in an experiment by the United States Department of Agriculture, calves were changed from colostrum to skimmilk on the fourth day of age with fair results.[70]

After the calf has been changed entirely to skimmilk, the allowance may be increased very gradually, if the calf is doing well. Not over 14 to 16 lbs. of skimmilk daily are needed, but if an excess is available after any pigs or poultry have been provided for, large vigorous calves may be fed somewhat more. Not more than 18 lbs. daily should be fed until the calf is 6 weeks old, but after this vigorous calves may have as much as they wish. If but a small amount of skimmilk is available, good gains can be secured on only 10 lbs. of skimmilk per calf daily, along with plenty of concentrates and good hay.[71]

If the supply is sufficient, skimmilk feeding should be continued for at least 6 months, but when the supply is scanty, thrifty calves can be weaned at 2 to 3 months and then be fed a calf starter.

For feeding with skimmilk any of the grain mixtures are satisfactory that have been previously suggested for feeding with milk. (1131) Experiments have shown clearly that for calves receiving a liberal amount of skimmilk, a concentrate mixture consisting chiefly or entirely of farm-grown grain is just as satisfactory as one containing a large proportion of protein-rich feeds.[72]

Sometimes fat or oil is mixed with skimmilk or reconstituted skimmilk, made from dried skimmilk, as a substitute for the fat in whole milk. However, the cereal grains, rich in carbohydrates, are cheaper and much more satisfactory. Ordinary plant oils, such as soybean oil or cottonseed oil, produce poor results, while calves do fairly well when lard or hydrogenated plant oil is added to the skimmilk.[73] The oil must be fed as an emulsion in the milk, or it is apt to cause indigestion and scours.

Minnesota and Missouri trials show that when an abundance of skimmilk is available, thrifty calves can be raised, after 2 to 3 weeks of whole milk feeding, on only skimmilk and alfalfa hay.[74] In the Minnesota test calves thus raised made normal gains and consumed 140 lbs. whole milk, 2,110 lbs. skimmilk, and 813 lbs. alfalfa hay to 6 months of age.

1138. Feeding buttermilk, whey, or reconstituted milk.—Fresh *buttermilk* that is sanitary and is not badly diluted is a good substitute for skimmilk in raising calves, and it may be used in the same manner. It is best not to begin changing calves from whole milk to but-

termilk until they are 4 weeks old, as buttermilk sometimes has a more laxative effect than skimmilk.

Whey can be used very successfully for calf feeding, when fed as recommended in Chapter XXIII. (889) If calves fed whey or reconstituted whey, made from dried whey, tend to scour, this can be prevented, according to Wyoming tests, by mixing one-quarter teaspoonful of slacked lime with each feeding.[75]

Sometimes *dried skimmilk* or *dried buttermilk* is mixed with warm water to make *reconstituted skimmilk* or *buttermilk*. This can be used satisfactorily in the same manner as ordinary skimmilk or buttermilk. (893) Dried skimmilk, dried buttermilk, and dried whey are also common ingredients in dry calf starters, or calf meals.

1139. Raising calves on nurse cows.—Where dairy by-products are not available on the farm, some use the "nurse-cow method" of raising calves with much success.[76] In this method 2 to 4 calves of about the same age and vigor are kept in a box stall with a cow, competing for her milk. The calves should be taught to eat a dry calf meal and hay as soon as possible and may be weaned, if necessary, at 2 to 3 months of age.

This system takes a minimum of labor and reduces the trouble from scours, if the number of calves is properly adjusted to the milk yield of the cow. During her lactation one cow may thus raise several calves to the weaning age. Often a hard milker or low tester can well be used for this purpose. New York tests indicate that a cow infected with mastitis can safely be used as a nurse cow, without infecting heifer calves that nurse her.[77]

1140. Raising calves on calf starters and a minimum of milk.—In market milk or condensary districts where no skimmilk, buttermilk, or whey is available, the calf starter method of raising calves is widely used. In this method the calves are given a good start on normal amounts of whole milk and are taught to eat a dry calf starter, or calf meal, and good hay as soon as possible. Then, if they are thrifty, the amount of milk is soon reduced and they are weaned entirely from fluid milk at 7 to 10 weeks of age. After this, they are fed only the calf starter, with plenty of first-class hay and with water to drink.

This method saves considerable labor in comparison with the feeding of reconstituted milk or of calf meal in gruel form, for there is no mixing and warming of a fluid food and washing and sterilizing of calf pails, after the calves are weaned. The results may be a little more variable with this method than when calves are raised on plenty of skimmilk. To secure the best results, the calves must be well started on the dry calf meal and hay before they are weaned from milk. Excellent-quality legume hay or mixed hay high in legumes must be fed, and if a calf is delicate or sickly, whole milk feeding must be continued until it is strong.

Some such schedule as the following should be followed under this plan: Feed a normal amount of whole milk during the first 3 weeks to Holstein, Brown Swiss, or Ayrshire calves and during the first 4 weeks to Jerseys and Guernseys. The maximum can be 10 lbs. a day for the former breeds and 7 lbs. for Jerseys and Guernseys. After this period, reduce the allowance for the larger breeds to 9 lbs. during the fourth week, 7 lbs. during the fifth week, 6 lbs. during the sixth week, and then gradually wean the calf during the next 7 to 10 days. In the case of a Jersey or Guernsey calf, reduce the milk allowance more gradually and do not wean the calf until 9 or 10 weeks of age, unless it is doing unusually well.

Until the calf is 3 months old, let it have all the dry calf meal it will eat, up to a maximum of 4 or possibly 5 lbs. a day, along with plenty of good hay. When the calf is about 3 months old, supply a simple "growing mixture," in addition to the more expensive calf starter. Any of the mixtures previously suggested for milk-fed calves will be satisfactory, which contain linseed meal, wheat bran, or other protein supplements. (1131) When the calf is 4 months

old, the calf starter can be discontinued and the cheaper mixture fed, along with the hay.

In this method not over about 350 lbs. of whole milk need be fed, in addition to the colostrum during the first 3 days, which is not marketable. To reduce the amount of whole milk used, the feeding of milk in this method is sometimes discontinued at an earlier age than stated. However, the calves then often gain poorly for a month or more, and become pot-bellied and scrawny. Later, they may make good gains and reach normal weight and height at 12 to 24 months of age.

Numerous experiments have shown that very satisfactory results are generally secured when calves are raised by the calf starter method, if a total of about 350 lbs. of whole milk, in addition to colostrum, is fed and plenty of good quality hay is supplied. For example, this method has been used very successfully at the New York (Cornell) Station during the past 20 years in extensive experiments in which various calf starters have been compared.[78] In these experiments, calves of the various dairy breeds have made satisfactory growth with this system. The gains to 4 months of age have usually been slightly greater than the normal rate in dairy herds. Similar results have been secured in numerous experiments elsewhere with dry calf starters or calf meals.[79]

When calves are raised by the calf-starter method, good results are secured with more uniformity if the feeding of whole milk is continued until the calves are 7 to 10 weeks old. However, if an effective antibiotic feed supplement is added to the milk, the results are usually satisfactory when milk feeding is discontinued at 5 weeks, and a total of only about 175 lbs. of milk is fed. If a calf is not growing thriftily, milk feeding should be continued longer.

1141. Formulas for calf starters.—Many different formulas for calf starters have been used successfully in the experiments with this method of raising calves. It was concluded in the New York experiments, for example, that no one calf starter proved to be consistently better than all others.

The calf starters commonly used have about 20 per cent protein and thus must include a rather large proportion of protein-rich supplements. A calf starter should be very rich in total digestible nutrients, and should therefore not have more than about 5 per cent of fiber. In a recent Kentucky experiment a calf starter containing only 16.6 per cent protein, fed with excellent alfalfa-bromegrass hay, gave about as good results as starters higher in protein.[80]

Most of the calf starters used earlier contained 20 per cent or more of dried skimmilk or equivalent amounts of fish meal, meat scrap, or tankage. Later experiments have shown that protein supplements of animal origin are not necessary in a calf starter, if a considerable part of the protein comes from properly cooked soybean oil meal and if the calves are fed about 350 lbs. of milk (not including colostrum).[81]

When less whole milk is fed and the calves are weaned before the age of 7 to 9 weeks, there should preferably be at least 5 per cent of dried skimmilk or other suitable feed of animal origin in the calf starter. Satisfactory results were secured in the New York trials with calf starters containing only 5 per cent of dried whey as the feed of animal origin. These starters also contained 14 per cent of soybean oil meal and 10 per cent of linseed meal, or else 20 per cent of linseed meal, along with 5 per cent of alfalfa meal and with mineral supplements and irradiated yeast in addition.

A calf starter is more palatable when the grain is ground coarse instead of fine.[82] Pelleting a calf starter or part of the ingredients did not increase the palatability or the value in Kansas, Kentucky, Maryland and New York tests.[83]

Yellow corn is an excellent grain to include in a calf starter, because of its vitamin A value. Ground or crushed oats is a popular ingredient, and is as satisfactory as the more expensive rolled oats, without the hulls. Other ground grain, such as grain sorghum, can be used in addition to corn and oats or as a

substitute for them. The addition of 5 to 8 per cent of cane molasses seems to improve the palatability of a calf starter slightly.

In a calf starter in which soybean oil meal provides much of the protein, 10 to 20 per cent of distillers dried solubles is a satisfactory substitute for dried skimmilk or dried whey and dried yeast. (955) Cottonseed meal, even that which is degossypolized, is less satisfactory than soybean oil meal as the chief protein supplement.[84]

To help insure a plentiful supply of vitamins and minerals, it is well to have in a calf starter 5 to 7 per cent of high-grade alfalfa meal or alfalfa leaf meal, 0.5 per cent of ground limestone, 0.5 per cent of bone meal or other safe phosphorus supplement, 0.5 per cent salt, and 0.025 to 0.05 per cent of irradiated yeast or 0.125 per cent of cod-liver oil concentrate.

The following are examples of calf-starter formulas which have proven very satisfactory:

(1) Cracked yellow corn, 19.475 lbs.; crushed oats, 20.0 lbs.; wheat bran, 15.0 lbs.; linseed meal, 10.0 lbs.; dried skimmilk, 5.0 lbs.; soybean oil meal, 14.0 lbs.; cane molasses, 5.0 lbs.; alfalfa meal, 7.0 lbs.; brewers' yeast, 3.0 lbs.; irradiated yeast, 0.025 lb.; ground limestone, 0.50 lb.; steamed bone meal or dicalcium phosphate, 0.50 lb.; iodized salt, 0.50 lb. (Dried whey can be used in place of the dried skimmilk, and the linseed meal or soybean oil meal increased slightly.)

(2) Yellow corn meal, 24.775 lbs.; crushed oats, 20.0 lbs.; wheat bran, 15.0 lbs.; linseed meal, 10.0 lbs.; soybean oil meal, 18.2 lbs.; cane molasses, 5.0 lbs.; alfalfa meal, 5.0 lbs.; irradiated yeast, 0.025 lb.; ground limestone, 0.50 lb.; bone meal or dicalcium phosphate, 1.00 lb.; salt, 0.50 lb.

(3a) For feeding with plenty of good alfalfa or other legume hay: Ground grain sorghum, 300 lbs.; cottonseed meal or soybean oil meal, 200 lbs.; wheat bran, 100 lbs.; steamed bone meal, 3 lbs.; salt, 3 lbs.

(3b) For feeding with poorer hay: Ground grain sorghum, 300 lbs.; cottonseed meal or soybean oil meal, 150 lbs.; wheat bran, 100 lbs.; alfalfa leaf meal, 50 lbs.; brewers' dried yeast, 25 lbs.; steamed bone meal, 3 lbs.; salt, 3 lbs.

When a total of about 400 lbs. of whole milk (not including colostrum) is fed per calf and care is taken to supply first-class hay, a very simple calf starter can be used. In Wisconsin experiments Guernsey and Holstein calves thus fed made normal gains on a calf starter containing only equal parts by weight of ground yellow corn, ground oats, wheat bran, and linseed meal.[85] Though these calves did not gain as rapidly as others fed skimmilk to 6 months of age, they would later make up all or most of this difference, if they were well fed up to calving time.

1142. Milk replacers or substitutes.—Many experiments have been conducted recently to devise milk replacers or substitutes for raising calves with no whole milk after only a few days of age.[86] Such milk replacers are usually fed in the form of a warm gruel, and in addition the calves are supplied a less expensive dry calf starter and good hay.

When the feeding of whole milk is discontinued at 10 days of age or less and a good milk replacer fed in gruel form instead, calves can usually be raised successfully. However, they often are less thrifty and grow less rapidly than those raised by the calf-starter method with a total of about 350 lbs. of whole milk. If well fed later, they tend to develop normally.

Several milk replacers are now made by feed manufacturers, and these should be used according to the directions which are supplied. The most efficient milk replacers generally contain a large percentage of dried skimmilk, dried whey or other dairy by-products, along with other feeds, vitamin supplements, minerals, and perhaps an antibiotic. For example, a satisfactory milk replacer used in New York experiments contained: 50 lbs. dried skimmilk, 30 lbs. dried whey, 7.76 lbs. dextrose, 5 lbs. oat flour, 4.9 lbs. brewers' dried yeast, 0.1 lb. irradiated yeast, 2.2 lbs. stabilized vitamin A sup-

plement, and 0.04 lb. trace mineral supplement.[87]

As Allen of the Wisconsin Station points out, the use of a milk replacer certainly does not provide better nutrition or reduce losses, in comparison with the calf-starter method and more whole milk. Also, the feeding of a milk replacer as a warm gruel requires more time and bother.[88] It takes at least 20 lbs. of a milk replacer to furnish as much nutrients and energy as in 100 lbs. of whole milk. He concludes that one cannot save enough money to pay for the extra trouble in using a milk replacer unless he can buy a 25 lb. sack of milk replacer for the net farm price received for 100 lbs. of milk.

1143. Self-feeding calves.—Since the self-feeder is used so successfully for pigs, experiments have been conducted to find whether or not calves can be raised satisfactorily by self-feeding them concentrates in addition to supplying milk and roughage.[89] These trials have shown that if calves or heifers are self-fed, free choice, such grains as corn and oats, and also linseed meal, wheat bran, and other protein supplements, they will usually eat much more of the protein supplements than they need. This will make the cost unduly high.

Also, even if the calves are self-fed a mixture containing the proper proportion of protein supplements, after 2 to 4 months they will often eat much more concentrates than they need and less hay than they should take. This is expensive, but even more important, the amount of hay may be so small that the calves may become unthrifty, due to a lack of the vitamins and minerals good hay provides. They may suffer from rickets and even have fits and convulsions.

By using a mixture of the proper proportions of chopped or ground legume hay and concentrates in a self-feeder this difficulty can be avoided, but the proportion of hay must be carefully adjusted, so that the calves will eat plenty of hay and yet make the desired gain.

III. Dairy Heifers

1144. Grow heifers well.—Rearing heifers after they are 6 months old is an easy task. Perhaps for this very reason, many are stunted for lack of proper feed and attention and fail to develop into profitable cows. Also, if a dairyman raises surplus cattle for sale, he soon finds that buyers do not want undersized heifers or cows, but they look for well-grown animals which give indications of large and profitable production. The proper development of the heifers is therefore an exceedingly important part of the dairy business.

As is shown in the following articles, it is entirely unnecessary to feed heifers expensively to secure good growth and development. All that is necessary is plenty of first-class roughage in winter and good pasture the rest of the year with only a minimum amount of a suitable concentrate mixture when needed.

1145. Nutrient requirements.—The nutrient requirements for growing dairy cattle have been discussed in detail earlier in this chapter. In considering the feeding of heifers after 6 months of age, the following special points about their nutrient requirements should be borne in mind.

Far too often, heifers are fed only fair or poor roughage in winter and are turned on pasture and allowed to shift for themselves in summer, with but little attention, even when the feed becomes scanty. Such neglect is perhaps due to the fact that the heifers are not bringing in any immediate cash income, and a lack of sufficient appreciation that the future income will depend on how the heifers are developed.

Heifers cannot make normal growth unless they receive an adequate supply of total digestible nutrients. Since hay and other roughages are bulky and relatively low in digestible nutrients, young heifers fed roughage alone, without grain or other concentrates, cannot consume enough of the bulky feed to provide sufficient nutrients for good growth. After they are a year old, their digestive tracts are well developed, so they can be wintered satisfactorily on roughage with little or no concentrates, if the roughage is of satisfactory quality.

Raising heifers on an abundance of

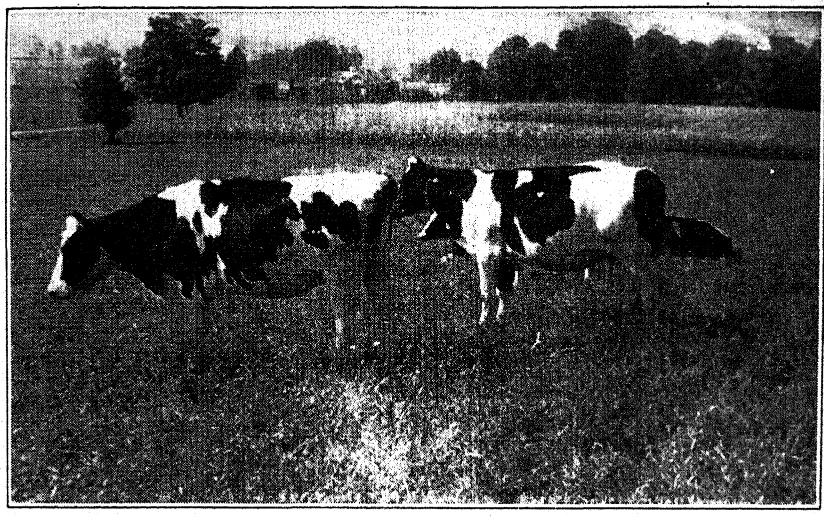
good hay and other roughage, with just enough concentrates to keep them growing properly, is nearly always much more economical than feeding them a large allowance of concentrates with less roughage. Heifers fed liberally on concentrates will make rapid growth and be sleek and fat, but such wasteful feeding is actually detrimental to their future usefulness.

It has been pointed out earlier in this chapter that there is more apt to be a deficiency of phosphorus than of calcium in raising heifers. Whenever there may be a lack of these or other minerals, a suitable mineral supplement should be supplied.

If heifers are fed early-cut, well-cured hay in winter, especially legume or mixed hay, and are on good pasture in summer, they will receive an abundance of vitamins.

1146. Levels of feeding.—Several long-time experiments are being conducted in this and other countries to determine the effects of different levels of concentrate feeding of heifers up to the first calving, upon milk production in successive lactations and length of productive life.[90] The results thus far secured show clearly that overfeeding heifers on concentrates, so that they become very fat before freshening, not only is exceedingly uneconomical but also is apt to be definitely injurious.

It is more difficult to get heifers that are thus fed in calf, and their milk production when they freshen is often very disappointing. Such overfeeding tends to produce a heavy, coarse build and to cause undue fat deposition in the udder. This may never disappear after the heifer freshens. The udder is apt to be fleshy and meaty, instead of being composed almost entirely of milk-secreting tissue.



WELL-GROWN HEIFERS ON FINE PASTURE

To reduce the cost of raising heifers and at the same time secure good growth and development, the heifers must have plenty of first-class pasture in summer and all the good roughage they will eat in winter. (From New York State College of Agriculture, Cornell University.)

Heifers that are fed up to calving on rations which supply a scanty amount of total digestible nutrients and net energy, but plenty of minerals and vitamins, do not grow at a normal rate and do not come into heat as early as those fed adequate rations. If such heifers are fed a much more liberal amount of concentrates than usual during their first lactations, they will be able to grow enough

to make up much of the difference in size. They may even produce nearly as much milk as normal in the first lactation, and if well fed in later lactations will continue to grow and may reach almost normal size.

The results are much different from this on most farms where heifers are badly underfed up to the time they freshen. Usually the heifers, which are small and poorly developed, are not fed with great liberality during their first lactation. Consequently, they become stunted, undersized cows, and their milk production is much less than it would have been if they had been developed properly.

In certain of the long-time experiments heifers which were grown more slowly than normal tended to live longer, because they matured more slowly. However, these experiments do not show that it would be economical to follow such a method in raising heifers, instead of developing them well up to the time of calving.

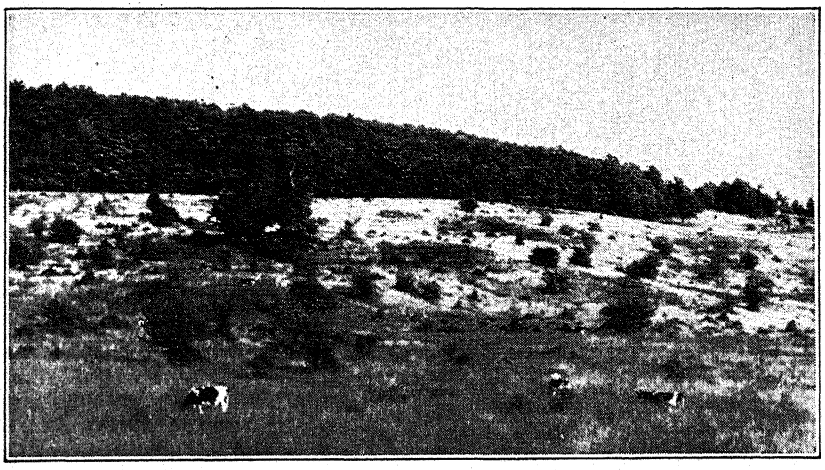
1147. Roughages for heifers.—In winter there is no better ration for heifers than legume hay or mixed hay high in legumes, with or without silage, and with a sufficient amount of a suitable grain mixture to keep them growing thriftily.

If possible, at least half of the winter roughage on the dry basis should be well-cured legume or mixed hay, for it supplies needed protein, calcium, carotene and vitamin D. If legume hay is not available, early-cut and well-cured grass hay should be used. Even such grass hay should be fed, if possible, along with some legume hay or with silage.

When there is little or no legume roughage in the winter ration, care must be taken to feed a sufficient amount of protein supplement to balance it properly. Also, a calcium supplement may be needed. **(1116)**

The importance of good hay for heifers is shown by New York tests.[91] Heifers fed poor-grade alfalfa hay with 6 lbs. of concentrates per head daily did not gain as rapidly as others fed only 3 lbs. of concentrates a day with U.S. No. 1 alfalfa hay. In another experiment young heifers would eat only 0.9 lb. a day of ripe bluegrass hay, while they consumed 4.1 lbs. of No. 1 mixed legume-grass hay.

If necessary, a limited amount of poorer roughage can be fed, along with



HEIFERS ARE OFTEN NEGLECTED ON POOR PASTURES

Often heifers are turned in summer on poor, unimproved pasture, such as this, and allowed to shift for themselves, with little attention. (From New York State College of Agriculture, Cornell University.)

good legume hay or with silage. Cut or shredded fodder or stover from corn or sorghums, cottonseed hulls, or even straw from the grains can be thus used. To get heifers to eat enough unpalatable roughage, diluted molasses may be poured over it. Thus fed on cut corn stover in a Wisconsin test, molasses was worth fully as much as ground corn per pound.[92]

Silage is excellent for heifers when fed as part of the roughage, along with legume or mixed hay. However, silage is not at all necessary if an abundance of good hay is fed. For heifers, just as with dairy cows, it requires about 3 tons of corn silage to equal 1 ton of legume or mixed hay in value.[93]

Heifers may be wintered satisfactorily on corn or sorghum silage as the only roughage, if a concentrate mixture is fed which furnishes plenty of protein,[94] but often they show a great desire for some dry forage. It is therefore wise to feed some hay or even dry fodder or stover from corn or the sorghums along with the silage.

1148. Concentrates for heifers.—All the grains may be used satisfactorily, when ground or crushed, for feeding heifers, and their relative values for this purpose will be about the same as for dairy cows. Other low-protein concentrates, such as hominy feed, dried beet pulp, dried citrus pulp, or molasses, can be substituted for grain. The use and relative values of these feeds have been discussed in the chapters of Part II.

Linseed meal, soybean oil meal, cottonseed meal, and wheat bran are the most commonly used protein supplements for heifers, but the other protein supplements that are satisfactory for dairy cows are likewise suitable for heifers. As has been shown in Chapter XXII, heifers over 3 to 4 months of age may even be fed cottonseed meal as the only concentrate without injury, if roughage is fed which supplies plenty of vitamins and if there is ample calcium in the ration. **(811)**

The use of urea as a substitute for part of the protein in rations for dairy cattle has been discussed in Chapter XXV. **(1019)**

1149. Feedng heifers from 6 to 12 months of age.—The feeding of milk or special calf meals is usually discontinued by the time heifers are 6 months of age, or even before. They should have an abundance of other feeds at this time, so that their growth will not be checked.

Numerous experiments have been conducted to find if heifers can be wintered satisfactorily on roughage alone.[95] These experiments show that when heifers are fed only roughage, even of good quality, before they are 10 to 12 months of age, they will not make normal growth. They will make up their growth to some extent later if well-fed, and may even reach normal size if fed liberally after they freshen. However, unless grain is unusually high in price in comparison with roughage, it is generally advisable to feed heifers under a year of age sufficient concentrates, in addition to an abundance of good roughage, so that they will make normal growth.

Experiments mentioned previously show that if heifers are fed an abundance of excellent legume hay, they may make normal growth when fed no concentrates after 8 months of age. **(1134)**

The amount of concentrates needed by heifers 6 to 12 months of age will, of course, depend on the quality and amount of roughage. With plenty of good roughage, 2 to 4 lbs. of concentrates per head daily should be enough, while with that of only fair quality 4 to 6 lbs. may be needed to keep the heifers gaining properly. Heifers 6 to 12 months of age should be fed 8 to 15 lbs. of hay a day, or 5 to 10 lbs. of hay and 8 to 15 lbs. of silage.

Whether it will be necessary to feed grain or other concentrates to heifers of this age on pasture will depend on how good the pasture is. If it supplies plenty of high-quality forage, they will make satisfactory growth on pasture alone.[96] However, on average pasture it is often necessary to feed a small amount of concentrates to keep them growing well. Whenever the pasture becomes scanty, it is especially important to provide plenty of other feed, including concentrates and also hay, silage, or green soiling crops. In

the spring when young heifers are first turned to pasture, it is best to continue feeding some hay until they get used to the lush, laxative green feed.

If the heifers are fed plenty of alfalfa, clover, or other legume hay as the only roughage, or if they are on good pasture which is kept well grazed, no protein supplements need be included in the concentrate mixture. Merely ground grain alone, even corn, is satisfactory. The mixture may be any desired combination of the common cereals.

Appendix Table VII gives a considerable number of concentrate mixtures containing various percentages of protein, which are excellent for dairy heifers. As shown in this table, concentrate mixtures containing 12 to 14 per cent total protein are recommended when only about half the dry matter of the roughage comes from legumes. With little or no legume roughage, the concentrate mixture should have 16 to 18 per cent protein.

1150. Feeding heifers over one year of age.—After heifers are a year of age they may be wintered satisfactorily, up to 3 or 4 months before calving, without concentrates, if fed either an abundance of good legume or mixed hay and silage, or else all the well-cured legume hay they will eat.[97] They will not carry as much flesh as some breeders desire, but if well fed before calving and during their first lactation period, they will reach normal size and weight.

With roughage of ordinary quality, it is necessary to feed a small amount of concentrates to keep heifers growing properly. If the roughage is fair in quality, not over 2 to 4 lbs. of concentrates should be needed up to 3 or 4 months before calving. At this time they should be fed more liberally, so as to supply nutrients for the development of the fetus and also so the heifers will be in good condition for high production during their first lactation. With plenty of good roughage, 4 to 5 lbs. of concentrates are sufficient at this time.

Yearling heifers do well on good pasture without any concentrates, if they can actually secure plenty of forage.[98] If the pasturage gets scanty, it should be supplemented with enough other feed—concentrates, hay, or silage—to keep them growing satisfactorily.

The same concentrate mixtures may be used for heifers of this age as for those up to a year of age. If desired, the proportion of protein supplement in the mixture may be reduced slightly, as heifers need somewhat less protein as they become older.

1151. Age for first calving.—Heifers that are well-grown for their age may be bred to calve at an earlier age than those which are undersized. Well-grown Holsteins may be bred to calve at 24 to 28 months; Brown Swiss a little later; Ayrshires and Guernseys, 23 to 27 months, and Jerseys, 22 to 27 months.[99]

Wisconsin studies indicate that, if heifers are properly developed, their total production up to a given age will be greater if they first freshen when slightly younger than is the practice in many dairy herds.[100] Holstein heifers in dairy-herd-improvement association herds that calved at 22 to 25 months of age produced on the average a total of 1,920 lbs. of butterfat to 7 years of age. Those that calved first at 28 to 29 months of age produced only 1,760 lbs., and those not calving until 30 to 31 months only 1,720 lbs.

Heifers that calve relatively early will not produce quite as much milk in their first lactation as when calving is delayed a few months. However, considering the additional cost of carrying a non-producing heifer a longer time, fairly early calving is generally more profitable. Also, if breeding is delayed too long, it is often much more difficult to get a heifer in calf.

Heifers that calve early must be fed liberally during their first lactation period, so that their growth will not be stopped. Otherwise, they will not reach normal mature size.

1152. Normal growth of dairy cattle.—In order to determine whether young dairy cattle are making the proper rate of growth for the particular breed, it is helpful to have a normal standard with which they can be compared. At

several experiment stations the weight and also the height at the withers have therefore been recorded each month during growth for young heifers and bulls of the chief dairy breeds.

The following table summarizes available data of this kind for young cattle up to 2 years of age. Records are included from the Iowa, Kansas, Missouri, Nebraska, South Carolina, and West Virginia Stations, and from the United States Department of Agriculture.[101] For each breed the averages represent data for a much larger number of animals at early ages than later ages. The average heights shown in the table are for smaller numbers of animals, and the number of bulls included in the studies was much less than of heifers. For the younger ages the average weights are for the following maximum numbers of heifers: Ayrshires, 390; Guernseys, 88; Holsteins, 885; and Jerseys, 507.

Normal growth in weight and height of dairy cattle

22	895	47.6			1376	55.3		49.3
24	990	48.1			1452	56.0		50.3

At one year of age the Ayrshire heifers averaged 518 lbs. in weight; the Guernseys, 490 lbs.; the Holsteins, 685 lbs.; and the Jerseys, 495 lbs. The gains during the first year averaged 1.62 lbs. per head daily for the Holsteins; 1.22 lbs. for the Ayrshires; 1.16 lbs. for the

Guernseys; and 1.20 lbs. for the Jerseys.

The gains during the second year were somewhat less rapid, averaging 1.15 lbs. per head daily for the Holstein heifers; 0.90 lb. for the Guernseys and Ayrshires; and 0.79 lb. for the Jerseys. After 2 years of age, increase in weight continues at a much reduced rate until dairy cattle reach mature weights at 6 or 7 years. Maximum height is reached somewhat earlier.

The bulls made distinctly more rapid gains than the heifers of the same breed and also were usually taller at a given age.

1153. Cost of raising heifers.—The cost of raising dairy heifers up to the time of first calving differs rather widely in various sections, depending chiefly on the prices of feeds. Feed and bedding usually make up about two-thirds of the total cost. To this expense must be added the initial value of the calf and the expenses for labor, shelter, interest, taxes, and miscellaneous items. From the gross cost should be deducted a credit for the manure produced.

The feed cost of raising heifers can be greatly reduced by providing plenty of excellent hay or hay and silage, as this decreases the amount of concentrates needed for growth. For example, in a recent United States Department of Agriculture experiment Holstein and Jersey heifers fed an abundance of excellent alfalfa hay or alfalfa hay and silage made normal gains to 2 years of age with a total of about 560 lbs. of concentrates and no milk after they were 60 days old.[58]

Except in sections where feed is cheap, the cost of raising heifers is often greater than the selling price of grade dairy heifers of ordinary quality. Care should therefore be taken to raise only heifers that are out of high-producing cows and that are sired by a good pure-bred bull. If more of such heifers are raised than are needed for replacements, they are the kind that will bring good prices. Heifer calves that are out of poor cows or those that are otherwise undesirable should not be raised, for they will not be worth the expense involved.

An interesting method of estimating whether a heifer calf will be a good milk producer has been developed by Swett and associates of the United States Department of Agriculture.[102] They have found that the size of the actual udder tissue in calves 3 to 6 months old is a fair indication of their future milk production, and have prepared a detailed grading system for selecting heifers for herd replacements on this basis.

Since feed is by far the largest item in the cost of raising heifers, the cost with various feed prices can be estimated from the data in the following table. This shows the amounts of feed needed to raise dairy heifers either to 2 years of age or to the time of first calving, as found in various studies.[103]

Amount of feed required to raise dairy heifers

	Whole milk	Skim-milk	Concen-trates	Hay and dry roughage	Silage, etc.	Pasture
	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Days
New York, various breeds	814 *	....	945	3,600	3,200	†
Maryland, various breeds	368 ‡	....	1,752	3,492	2,208	312

Ohio, Jerseys	465	3,015	1,382	2,041	2,884	281
Louisiana, Holsteins	827	2,775	896	2,589	1,934	†
Oregon, various breeds	552	1,209	230	3,260	1,180	358
Missouri, Holsteins	293	1,907	1,416	3,719	1,436	317

* Includes both whole milk and some skimmilk.
† Number of days of pasture not stated.
‡ In addition, nurse cows were used for some of the calves.

The New York and Maryland data represent the methods used in raising calves in the market-milk districts of

the eastern states. In the other studies considerable amounts of skimmilk were fed. The amounts of concentrates were low for the Louisiana and Oregon heifers, chiefly because pasture could be provided over a longer season than is possible in the central and northeastern states.

IV. The Bull

1154. Bred-for-production sires essential.—A dairyman cannot expect to improve the productive capacity and profitableness of his herd unless the heifers he raises are sired by a bred-for-production bull. The sire should be selected primarily on the basis of actual records of production of his immediate ancestors and their offspring, and not chiefly because of their show-ring winnings. Due attention must also be given to the conformation and type of the bull and his ancestors. If a poor bull is used, it will take years of constructive breeding to undo the damage.

As the average production of the cows in a herd increases, it becomes more and more difficult to select a bull whose daughters will be better than their dams, or that will even maintain a high level of production in the herd. In such herds it is especially desirable to use a "proved sire," whose ability to transmit high production has been definitely proved by the actual records of his daughters in comparison with the records of their dams.

Relatively few proved sires of superior merit are available, and therefore the average dairyman cannot himself own such a bull. Fortunately, the recent rapid development of artificial breeding associations in this country has revolutionized dairy cattle breeding. In most of our dairy districts, even a dairyman with a small herd can now, at moderate expense, have his cows inseminated with semen from bulls of outstanding transmitting ability.

1155. The young bull.—The same principles apply in the rearing of the young bull as with heifers, and the same methods of feeding can be used, except that it is wise not to limit the amount of milk so much as to check his growth. A young bull should always be fed so as to make good growth and reach normal size. One which has been stunted by insufficient feed may sire just as large calves, but a purchaser does not desire such an animal. He never knows whether the small size is due to heredity or to scanty feed.

Sexual maturity was delayed 4 to 14 weeks in New York and Pennsylvania experiments when bull calves were raised on rations that supplied only 60 to 75 per cent as much total digestible nutrients as advised in the feeding standards for growing dairy cattle.[104] Also, on the scanty rations the amount and quality of semen produced was lowered.

So far as is known, the protein, mineral and vitamin requirements of a young bull are the same as for a heifer. One should guard against any deficiency of vitamins or minerals, which might injure the health of the bull or lower his future breeding efficiency. However, there is no advantage in using special vitamin or mineral supplements, unless there is an actual deficiency in the ration.

In experiments by the United States Department of Agriculture bulls were raised on rations low in carotene, in which the only roughage was poor-quality timothy hay.[105] To these rations were added various amounts of vitamin A supplements to determine the requirements. It was found that decided physical symptoms of vitamin A deficiency usually appeared before the reproductive performance of a bull was lowered. Some of the bulls even continued to breed after they had become blind because of vitamin A deficiency.

After 5 to 6 months of age, when a bull calf should be separated from the heifers, he should have a somewhat larger amount of concentrates than a heifer. This is because a young bull makes more rapid gains than a heifer and consequently needs more nutrients. If well grown, a bull should be sufficiently mature for very light service at 10 to 12 months of age, but not more than 1 or 2 services in any one week should be permitted until he is 2 years old.

The bull should be halter broken as a calf, and at about 1 year of age should have a stout ring inserted in his nose. When he is about 2 years old this should be replaced by a larger one, and the ring must never be allowed to wear thin. He should be so handled from calfhood that he will recognize man as his master, and he should never be given an opportunity to learn his great strength. Stall and fences should always be so strongly built that there is no possibility of his learning how to break loose.

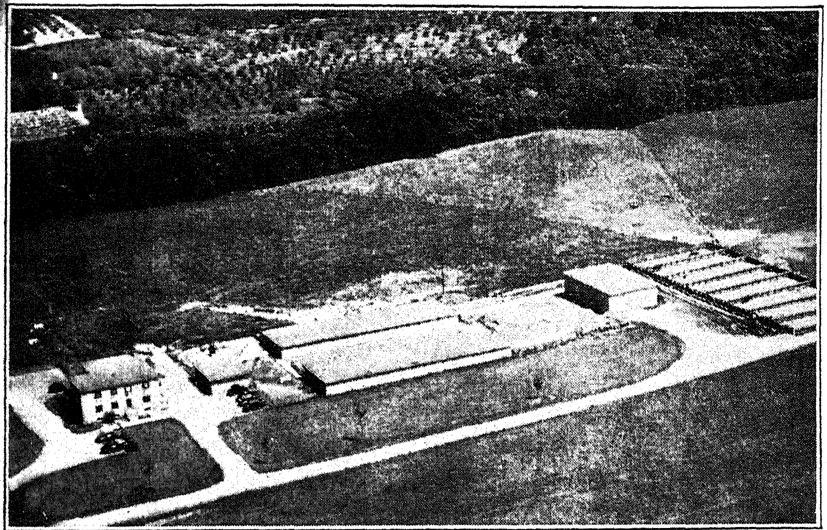
1156. Feeding the bull in service.—The bull in service should be fed good roughage and sufficient concentrates to keep him in thrifty condition, but not fat.

It was found in a New York experiment that to maintain the weights of bulls in heavy service satisfactorily, 8 to 11 per cent more total digestible nutrients were required than the higher set of recommendations made in the Morrison standards for the maintenance of dairy cows.[106] Based upon these experiments, feeding standard recommendations for total digestible nutrients were proposed, which are followed in the feeding standards given in Appendix Table III of this volume.

In these New York trials, the bulls needed about 0.4 to 0.5 lb. of concentrate mixture daily per 100 lbs. live weight, along with 0.9 to 1.0 lb. of hay per 100 lbs. weight. When fed only as much total digestible nutrients as required to maintain dry dairy cows, the bulls lost weight, but the volume or quality of the semen was not lowered in 90-day periods.

Good legume hay or mixed legume-grass hay is unexcelled as roughage for bulls. When hay is the only roughage, 15 to 20 lbs. a day is usually fed, depending on the size of the bull.

Opinions differ concerning the feeding of silage to bulls in service. Some advise feeding no more than 10 to 15 lbs. of silage a day, and believe that a



NEW YORK DAIRY CATTLE BREEDING CENTER

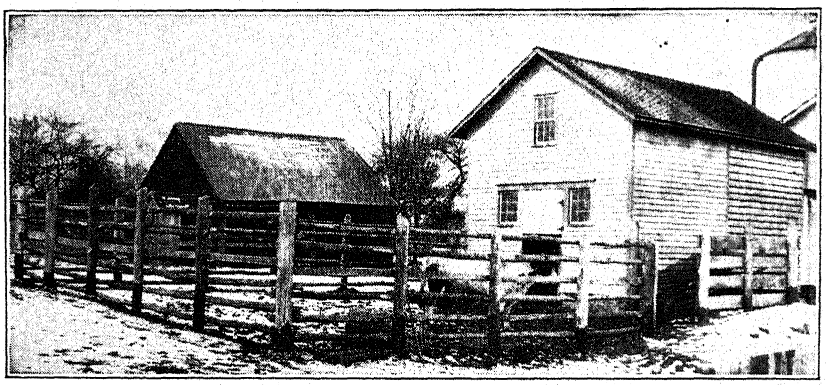
Airplane view of the Dairy Cattle Breeding Center at Cornell University, conducted cooperatively by the New York Artificial Breeders Cooperative, Incorporated, and the Animal Husbandry Department of the University. Laboratory and office building at left, one-story bull barns in center, and paddocks at extreme right. Semen produced here is distributed state-wide to local Artificial Breeding Associations, which breed over one-fourth of all the dairy cows in the state.

large amount tends to make a bull paunchy, so that he will be clumsy and slow at service. However, in recent Pennsylvania and Wisconsin trials bulls have been fed as much as 4 lbs. of hay-crop silage per 100 lbs. live weight with no impairment of breeding ability or quality of semen.[107] In the Wisconsin test bulls were maintained in satisfactory breeding condition on 45 lbs. of silage and 25 lbs. of alfalfa-bromegrass hay per head daily, without any concentrates.

Pasture is excellent for bulls, and if a safely fenced pasture paddock can be provided, the cost of feed during the growing season can be thus reduced. However, experiments have shown that the semen production is as good from bulls fed good hay, without pasture, as when pasture is furnished.[108]

A bull does not need nearly so much protein in his ration as a high-producing cow in milk, and should be fed the same sort of concentrate mixture as is used for dry cows or growing heifers. In a New York experiment it was found that a concentrate mixture having only 12 per cent of total protein was just as satisfactory as one higher in protein, when fed with good-quality mixed grass-and-legume hay having only 10 per cent legumes but containing 8.9 per cent protein. Similar results were secured in a New Jersey experiment.[74]

Differing from the opinions of certain Russian investigators,[109] it seems safe to conclude that when bulls are fed reasonably good roughage, the quality of protein in the concentrate mixture is not important. In a New York experiment with 18 bulls used in artificial insemination, bulls fed timothy hay as the only roughage produced about as much and as good semen with corn gluten feed as the only protein supplement, as when better-quality protein was provided by dried skimmilk or soybean oil meal.[110]



SAFETY BULL PEN WITH BREEDING CHUTE AND BREEDING RACK

This bull pen is equipped with a breeding chute and a breeding rack at the right, next to the shed, so that it is not necessary to handle the bull at time of service. The bull can exercise at will in the strongly-fenced pen. Note the steel oil drum in the pen near the corner. The bull plays with this and bunts it about, thus getting more exercise. (From Goodman, New York State College of Agriculture, Cornell University.)

There is no need to feed a complex concentrate mixture to bulls, or to add vitamin supplements or a complex mineral mixture to ordinary good rations. In a New Jersey experiment one group of bulls was fed a very simple concentrate mixture with mixed timothy-and-clover hay of average quality from the age of 18 months until they were about 3 years old.[111] Another similar group was fed a very complex concentrate mixture with the same kind of roughage.

The simple mixture consisted of ground yellow corn, corn gluten meal, dried beet pulp, and cane molasses, with

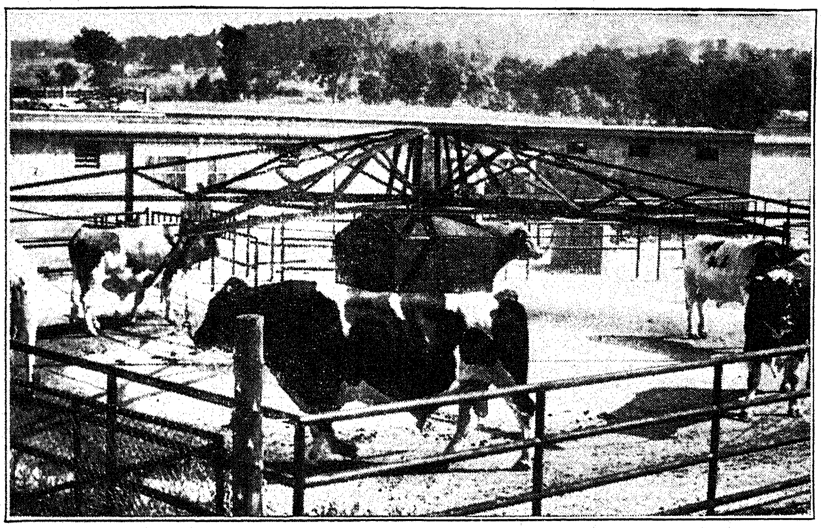
1 per cent iodized salt. This mixture had only 12 per cent total protein. Also, the protein in the mixture would be of poor quality for non-ruminants.

The complex mixture contained corn, oats, linseed meal, soybean oil meal, wheat bran, dehydrated alfalfa, cane molasses, limestone, bone meal, dried brewers' yeast, fish liver oil, irradiated yeast, and a mineral supplement supplying manganese, iron, copper, and cobalt. It thus supplied protein that would be of better quality for non-ruminants, and also contained special calcium, phosphorus, trace mineral, and vitamin supplements.

The bulls did not grow quite so rapidly on this complex concentrate mixture as on the simple one. Also, feeding the complex mixture did not make any appreciable difference in the quality of semen produced. The feed cost for the bulls fed the complex mixture was about 50 per cent greater than for those fed the simple mixture.

New York experiments showed that a deficiency of vitamin A in a ration for mature bulls must be so serious and so long-continued that it will produce decided physical symptoms of the deficiency before semen production is impaired.[112]

In another New York experiment there was no benefit from adding to an ordinary ration for bulls heavily used in artificial insemination, either wheat germ oil as a vitamin E supplement or shark liver oil as a vitamin A supplement.[113] In other experiments there has been no advantage in adding dehydrated young grass or sprouted oats to rations for bulls.[114]



ELECTRIC BULL EXERCISER

In this electric bull exerciser at the New York Dairy Cattle Breeding Center, 6 bulls are exercised at a time. (From New York State College of Agriculture, Cornell University.)

The results of these experiments agree with the results previously summarized that have been secured in experiments with dairy cows and dairy heifers. The data indicate that for dairy cows, heifers, or bulls high-quality protein is not needed in the concentrate mixture when roughage of ordinary good quality is fed. Also, special mineral and vitamin supplements are not needed, unless the roughage is actually deficient in a mineral nutrient or in carotene.

1157. Care of the bull in service.— Except perhaps in unusually cold climates, the best quarters for a bull are a well-built open shed with an adjoining

roomy paddock where he may exercise. This should be constructed as a "safety bull pen," with breeding chute and breeding rack so arranged that the necessity of handling the bull at time of service is eliminated. In such quarters a mature bull, even a vicious one, can be used in safety.

Though this open-air treatment is admirable for the health of the animal, it results in a heavier and rougher coat of hair, and hence breeders offering animals for sale usually prefer to keep the bulls in comfortable box stalls, turning them out only on fair days. Rather than confine the bull in isolation, it is well to have his stall so located and built that he can see the other members of the herd. The hoofs of a bull spending most of his time in the stall need regular trimming.

Louisiana experiments show that continued very hot weather greatly reduced the quality of semen and the fertility of bulls.[115]

It is generally advised that to keep a bull healthy and a sure breeder he should have plenty of exercise. No experimental results are available to show the effects of no exercise in consecutive years upon bulls confined to stalls. In a recent Michigan 6-month test there was no appreciable advantage from exercising confined bulls on a mechanical exerciser daily, except Sundays, but in other experiments exercise has been beneficial.[116]

Some dairymen who have two or more dehorned bulls turn them into one paddock, where they get plenty of exercise tussling with each other. Others exercise the bull on a tread power, where he may run the separator, pump water, do other useful work, or run the power for exercise only. Still others fix a long sweep on a post and tie the bull to it, so he will walk around in a circle.

Another device is a light cable stretched between two high posts, the bull being attached to it by a sliding chain so that he is able to walk back and forth along the cable. Electric bull exercisers, which are motor driven devices that lead bulls in a circular path, are convenient for breeders having several bulls.

From the standpoint of safety it is always desirable to dehorn the bull. Often breeders dislike to do this, because in the opinion of some it detracts from the appearance of the animal. In reaching a decision on this point one should bear in mind that many men have been killed by bulls with horns, who might have otherwise escaped.

A bull should always be handled with a strong, safe staff attached to the ring in his nose. Even with a quiet, peaceable bull, safety lies only in handling him without displaying fear and yet watching him carefully every minute. Nearly all the accidents occur with "quiet" bulls that have been too much trusted.

A good sire should be retained in the herd until it is necessary to make a change to prevent inbreeding. If he has proved to be a desirable sire and if he is still potent, he should be sold to some other breeder. No commoner mistake is made than discarding a likely bull at 3 to 4 years of age, before his heifers have come into milk to demonstrate how valuable a sire he may be.

QUESTIONS

1. State 5 essentials in rations for raising dairy cattle.
2. Discuss the protein requirements of dairy calves, considering both amount and quality of protein.
3. What has been found out concerning the need for fat?
4. State the importance of each of the following minerals for young dairy cattle: (a) Salt; (b) calcium; (c) phosphorus; (d) iodine; (e) other trace minerals.
5. How can the vitamin A needs of dairy calves be readily met?
6. Under what conditions should a vitamin D supplement be fed?
7. Discuss the needs for other vitamins.
8. Has the use of vitamin pills or capsules been beneficial?
9. What have experiments shown concerning the use of (a) antibiotic feed supplements; (b) surfactants; (c) arsonic supplements?
10. Would you use cud inoculation in raising dairy calves?
11. Discuss the importance of water for dairy calves.

12. State the important points in caring for a calf after birth.
13. Discuss the housing of dairy calves.
14. Tell how a dairy calf is started on whole-milk feeding.
15. What is the advantage and the disadvantage of nipple pails?
16. What sort of concentrate mixtures should be used for calves fed whole milk?
17. Discuss the importance of good-quality hay for calves.
18. Discuss the use of silage for calves; of pasture.
19. Describe the method of raising calves on skimmilk, stating the sort of concentrate mixtures that are most economical for feeding with skimmilk.
20. Discuss the use of the following for raising dairy calves; (a) buttermilk; (b) whey; (c) reconstituted milk.
21. Describe the "nurse-cow method" of raising cows.
22. Describe the raising of calves on a dry calf starter and a minimum amount of whole milk.
23. What sort of a formula should be used for a calf starter?
24. What is the advantage of the calf-starter method over the feeding of a gruel?
25. With the present price received for milk in your area, is the use of a milk replacer economical?
26. Discuss the nutrient requirements of dairy heifers.
27. What roughages and what concentrates are used most commonly for heifers in your region? What improvements can you suggest in the usual methods of feeding heifers?
28. Describe: (a) The feeding of heifers from 6 to 12 months of age; (b) the feeding of heifers over one year of age.
29. Discuss the age for first calving of heifers.
30. About how much should a Holstein heifer weigh at 1 year of age; a Jersey heifer?
31. Discuss the cost of raising heifers.
32. How would you select a bull to head a herd of high-producing grade cows?
33. State the most important points in the feed and care of a young bull.
34. Discuss the feed and care of the bull in service.

CHAPTER XXVIII

GENERAL PROBLEMS IN BEEF PRODUCTION

I. Nutrient Requirements of Beef Cattle

1158. Modern beef production requires scientific feeding.—Beef cattle in this country must now be fed more scientifically than a generation ago, because most of those fattened for our markets are much younger. Since they are still growing rapidly in protein tissues and skeleton, they need a more liberal supply of protein and minerals than do older cattle. Also, they are more apt to suffer from a lack of vitamins. In these modern methods of beef production, scientific feeding is necessary to avoid deficiencies and to secure efficient results.

Years ago, beef cattle were commonly raised to the age of 2 or 3 years before they were fattened for market. They made most of their growth on cheap pasture and were usually carried through the winters on roughage without any concentrates whatsoever. These well-grown cattle, 2 years old or more, were brought from the western ranges or other pasture districts to sections of the country where grain was cheaper, and there fattened for market.

Now, the cattle raised for beef on farms in the corn belt and eastward are generally fattened as they grow. Such cattle are fattened for marketing at 10 to 18 months of age as "baby beeves" or "fat yearlings." Some are even sold for slaughter at weaning time or soon afterwards as "heavy fat calves."

On the western ranges, where three-fourths of our beef cattle are produced, a considerable proportion of the calf crop is now marketed as feeder calves. These are fattened for market in the corn belt and other grain-growing regions by one of the methods described later. Except for the heifers needed for replacements in the breeding herds, most of the rest of the young cattle in the range districts are sold as yearlings in the fall of the following year, instead of being grown under range conditions to 2 years of age or more.

The pronounced change in the age at which beef cattle are marketed for slaughter has come about because of two factors: First, consumers desire rather small cuts of beef and want beef which is tender and has a minimum of waste fat. Second, as is shown later in this chapter, cattle fattened when young produce much more economical gains than those which are older. (1195)

1159. Nutrient requirements of various classes of cattle.—Before discussing in detail the requirements of beef cattle for the various nutrients, let us consider the differences in the general requirements for the various classes of beef cattle.

The nutrient needs of beef breeding cows are far different from those of dairy cows, for their milk yields are much lower. Also, they are usually dry during the winter and produce their milk while on pasture. It is shown in the next chapter that beef cows may be wintered entirely on roughage, if it is of fairly good quality and if enough legume forage is fed to meet their limited need for protein. (1211) Normally, beef cows need no concentrates during the pasture period.

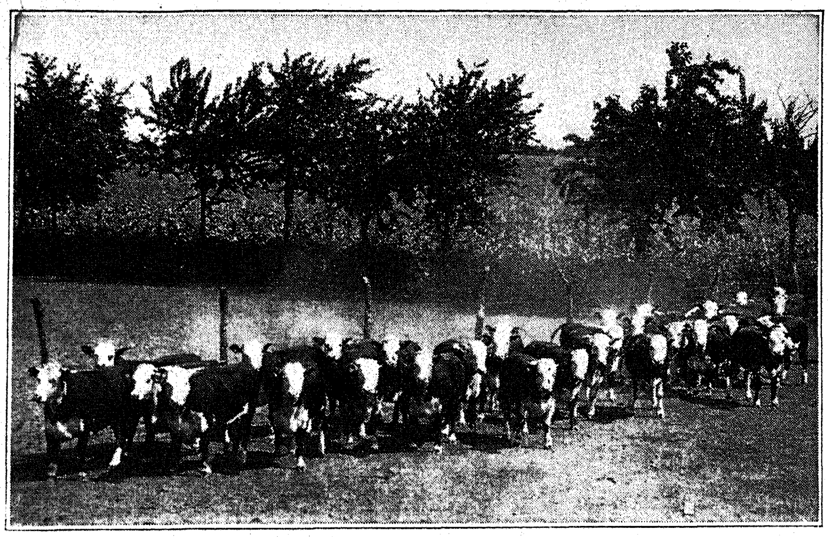
When calves or yearlings are being carried through the winter to be fattened later, they may likewise be fed entirely or chiefly on roughage, if it is of good quality. As is shown in the next chapter, whether or not it will be profitable to feed grain in addition to good roughage will depend on the method of fattening that is to be followed.

The requirements for fattening cattle are much different from those for breeding cows or for wintering young stock. To enable fattening cattle to make rapid

gains, they must receive rations rich in digestible nutrients and net energy. Except when grain is unusually high in price compared with roughage, a liberal amount of grain should generally be fed to cattle being fattened in dry lot. Unless this is done, they will make less rapid gains and will not reach as good a finish. Especially with calves and yearlings, good gains cannot be expected unless the ration provides ample protein, minerals, and vitamins.

carotene needed per head daily by the various classes of beef cattle.

As a guide in selecting efficient rations for the different classes of beef cattle, example rations, adapted to various conditions, are given in Appendix Table VII. In the paragraphs which immediately precede the example rations in this table, the changes are indicated which can be made to adapt the rations to local conditions. Additional information concerning desirable rations for various



YOUNG CATTLE NEED AMPLE PROTEIN, MINERALS, AND VITAMINS

Cattle fattened for market when young need a much more liberal supply of protein, minerals, and vitamins than do older cattle.

classes of beef cattle is given in Chapter XXIX.

1160. Feeding standards and example rations.—The nutrient requirements of beef cattle of the various ages and classes are shown in the feeding standards presented in Appendix Table III. These state the amounts of dry matter, digestible protein, and total digestible nutrients recommended per head daily for cattle of various weights. For the computation of rations on the net energy basis, net-energy recommendations are also given. These net-energy figures are not used when rations are computed on the basis of total digestible nutrients. The standards also include the amounts of calcium, phosphorus, and

The recommendations made in the feeding standards presented in this volume are based chiefly on studies by the author of the many experiments conducted by the American experiment stations to study the requirements of beef cattle. Careful consideration has also been given to the recommendations made by a special committee of the National Research Council in their report on "Recommended Nutrient Allowances for Beef Cattle."[1]

In the report of this committee the amounts of feed recommended per head

daily are given in terms of air-dry feed, instead of dry matter. The author prefers to state the allowances in terms of dry matter, because of the considerable differences in dry-matter content of such feeds as hay or cured fodder in humid and semi-arid districts. Also, in the report of this committee, a range is not indicated in the requirement for the various nutrients. For the reasons that have been pointed out previously, the author prefers to show a range in the amounts of dry matter, digestible protein, and total digestible nutrients or net energy. (317)

1161. Amounts of protein required.—Numerous experiments have proved that fattening cattle and other beef cattle do not need nearly so much protein as was recommended in the Wolff-Lehmann and other old feeding standards. This fact is of great financial importance in beef production, because protein supplements ordinarily cost much more per ton than grain.

Many feeding trials have been conducted by the experiment stations to find whether or not a protein supplement is needed to balance various rations for fattening cattle. In other experiments the results have been determined from feeding different amounts of protein supplements in practical rations for fattening cattle. Less information is available concerning the protein requirements for beef breeding cows or for wintering young beef cattle. Because of the limitations of space, the many experiments bearing on the protein requirements cannot be reviewed here. Only certain general conclusions can be given.

The amounts of protein recommended in the Morrison standards are based chiefly on studies by the author of the experiments on this subject. These include trials over several years by the author and associates to determine the protein requirements for fattening yearling cattle.[2]

No smaller amounts of digestible protein are recommended in these standards than have actually been proven to give good results under practical farm conditions. In certain other feeding standards for beef cattle, smaller amounts of protein have been recommended for some classes of cattle, largely on theoretical grounds rather than on the results of actual feeding requirements. The author prefers to follow a conservative policy in all feeding standard recommendations and to base his advice on the results of experiments conducted under practical conditions.

Feeding somewhat less protein to fattening animals than advised in the standards will not produce any serious effects. It may even be economical when protein supplements are very expensive, in comparison with grain. It is believed, however, that if the protein supply is reduced much, the gains are apt to be lessened, and more feed required per 100 lbs. gain. Also, there will be a tendency for the cattle to sell at a lower price, because of less satisfactory finish.

1162. When is a protein supplement needed?—The protein content of the roughage will chiefly determine whether a protein supplement is required, and also the amount advisable, if one is needed. Legume hay, legume silage, legume pasture, and even young, actively-growing grass pasture are all so rich in protein that fattening cattle make good gains on plenty of such roughage with corn or other grain, without any protein supplement.

In rations for fattening cattle the kind of grain is also an important factor. A supplement may be needed when cattle are fattened on corn or other low-protein grain, while no supplement may be required if the grain is oats, wheat, or barley, which have more protein than corn. The example rations given in Appendix Table VII show when a protein supplement is needed for the various classes of beef cattle, and also the approximate amounts required to balance the ration.

If the roughage for fattening cattle is entirely non-legume, such as corn or sorghum silage, grass hay, or corn fodder, good results cannot be secured without a protein supplement. Also, a pro-

tein supplement is needed when beef breeding cows or young cattle are wintered on such roughage.

Several experiments have shown the importance of adding a protein supplement to a protein-poor ration for fattening cattle.[3] The addition of the supplement not only greatly increases the rate of gain, but it also reduces the amount of feed required per 100 lbs. gain and raises the selling price of the cattle. When care is taken to feed no more protein supplement than is actually needed to balance the ration, each 100 lbs. of such a supplement as linseed meal, soybean oil meal, or cottonseed meal will be equal in value to 250 to 300 lbs. of grain or grain equivalent. This value considers not only the saving in amount of feed per 100 lbs. gain, but also the higher selling price, because of better finish.

1163. Adding a protein supplement to grain and legume forage.—Whether it will pay to add a protein supplement to a ration of grain and legume forage for fattening cattle will depend on the amount of legume forage actually eaten, on the protein content, and on the age of the cattle.

Good alfalfa hay provides plenty of protein when 2-year-old cattle are full-fed corn grain and such hay. The same is true of soybean hay and cowpea hay, which have about as much protein as does alfalfa. For example, the addition of linseed meal or cottonseed meal to corn and alfalfa hay in Nebraska trials did not increase the gains of 2-year-old steers, raise the selling price, or reduce the feed required per 100 lbs. gain.[4]

Younger fattening cattle need somewhat more protein for maximum gains. Hence, the addition of a protein supplement to a ration of corn and a liberal amount of alfalfa hay will usually increase the gains of calves and yearlings a trifle. However, the saving in amount of feed required per 100 lbs. gain will not generally be enough to give the supplement a much higher value than corn per ton. For example, in 7 experiments calves fed only corn and alfalfa hay ate an average of 13.3 lbs. corn and 6.3 lbs. alfalfa hay a day and made the very satisfactory gain of 2.28 lbs. per head daily.[5] Others fed 1.1 lbs. a day of linseed meal or cottonseed meal in addition gained 2.38 lbs. On the average, however, each 100 lbs. of protein supplement saved only 73 lbs. corn and 60 lbs. hay. Under usual price conditions, it did not pay to feed the supplement.

When calves or yearlings full-fed on corn eat less than 4 to 6 lbs. a day of alfalfa hay, there will be more advantage from adding a protein supplement. Thus, in 3 Nebraska trials with yearlings, the addition of 1 lb. of cottonseed meal per head daily to a ration of 13.9 lbs. corn and 4.2 lbs. alfalfa hay increased the gain from 2.22 lbs. a day to 2.38 lbs.[6] Each 100 lbs. of cottonseed meal saved 131 lbs. corn and 40 lbs. of hay.

When cattle are full-fed corn with alfalfa hay as the roughage, the benefit from adding a protein supplement is greatest during the latter part of the fattening period, as they then eat less hay and more corn. Also, the protein supplement helps keep them on full-feed, when their appetites might otherwise lag.

When red clover or lespedeza hay is fed with corn to fattening cattle, there is more advantage in adding a protein supplement, because these hays are lower than alfalfa in protein. A ration of red clover hay and corn does not supply quite enough protein for the best results in fattening even 2-year-old cattle. For example, in 5 experiments 2-year-old steers fed an average ration of 18.7 lbs. shelled corn and 9.9 lbs. clover hay made the fairly satisfactory gain of 2.08 lbs. a day. Adding a protein supplement increased the gain to 2.38 lbs., on the average.[7]

When the grain fed with legume hay is barley, wheat, or oats, there is less need of adding a supplement than with corn, because of the higher protein content of these grains.[8]

1164. Supplement needed with part non-legume roughage.—When legume hay or legume silage forms only part of the roughage for fattening cattle, the amount of protein in the ration is

correspondingly decreased and the need of a supplement is greater. The amounts of supplement needed for various combinations of roughages and grain are indicated in the example rations given in Appendix Table VII. The exact amount required in any particular ration can readily be found by computing a ration which is balanced according to the feeding standards.

When fattening cattle are fed all the corn or sorghum silage they will eat in addition to hay and corn or other grain, the silage is so palatable that they will generally eat but 2 to 4 lbs. of hay a day, even when it is legume hay of good quality. This small amount of legume hay is insufficient to balance the ration fully, and therefore the gains will be increased considerably if a supplement is added.

A protein supplement is especially needed in such a ration for fattening calves, because of their higher protein requirements. For example, in 8 experiments the addition of 1.5 lbs. per head daily of linseed meal or cake to a ration of corn grain, corn silage, and alfalfa hay increased the daily gain from 2.01 lbs. to 2.29 lbs. and raised the selling price 42 cents per 100 lbs.[9] (In 6 of the trials the calves were fed a mixture of corn and oats while they were being started on feed.) In each of the tests the net return per head over feed costs was greater for the supplement-fed calves, the average net return being $2.75 more. In these experiments each 100 lbs. of linseed meal was worth as much as 230 lbs. of corn grain, considering all factors.

A PROTEIN SUPPLEMENT IS NEEDED WITH CORN SILAGE

When fattening cattle are fed corn or sorghum silage, a protein supplement is needed to balance the ration.

Similar results were secured in trials with fattening calves in which 0.9 lb. cottonseed meal per head daily was added to a ration of corn grain, sorghum silage, and alfalfa hay.[10] In these trials each 100 lbs. of cottonseed meal was worth as much as 287 lbs. of corn.

A ration of corn grain, corn silage, and alfalfa hay is more nearly balanced for older cattle. In 6 experiments the addition of 2.3 lbs. per head daily of protein supplement to this ration for fattening 2-year-old steers increased the daily gain from 2.22 lbs. to 2.34 lbs.[11] A greater amount of protein supplement was fed in these trials than later experiments have

shown to be necessary. Partly because of this, the use of the supplement was not profitable. It probably would have paid to feed 0.50 to 0.75 lb. of supplement per head daily.

With red clover or mixed hay in place of alfalfa hay, fed along with corn silage and corn grain, a protein supplement is needed even for 2-year-old cattle. Thus, in 14 trials the addition of cottonseed meal or linseed meal to a ration of shelled corn, red clover hay, and corn silage increased the daily gain of 2-year-old steers from 2.1 lbs. to 2.5 lbs.[12] Also, the selling price of the cattle was raised 33 cents per hundredweight and the net return over cost of feed was greater.

When a ration is deficient in protein, it is important to add sufficient protein supplement to balance it properly. This is well shown by 4 Oklahoma experiments in which fattening calves were full-fed ground corn and sorghum silage, with only 1 lb. of alfalfa hay per head daily.[13] Calves fed 1.5 lbs. of cottonseed cake gained 0.2 lb. more a day than others fed but 0.5 lb., yielded better-finished carcasses, and gave a 40 per cent higher net return.

1165. Quality of protein.—For the reasons explained in Chapter V, the quality or kind of protein is of nowhere near as great importance in feeding beef cattle as it is for swine or poultry. (**112**) When beef cattle are fed even a rather limited amount of legume roughage, the ration will usually provide protein of adequate quality. On the other hand, if the ration contains little or no legume roughage, and especially if the roughage is of poor quality, attention should be given to the quality of protein supplied by various protein supplements.

Experiments have shown, for example, that corn gluten meal is decidedly less efficient than such supplements as linseed meal, soybean oil meal, or cottonseed meal in balancing a ration of grain and non-legume roughage for fattening cattle. (**715**) In such rations this corn by-product should therefore be combined with supplements that provide protein of better quality.

Differing from the results with cattle full-fed on corn grain, corn gluten meal has been fully equal to linseed meal or soybean oil meal when 1 lb. of supplement per day has been added to sorghum silage for wintering beef calves or yearlings. This may indicate that although sorghum forage is low in protein, the quality of the protein is better than that of corn grain.

For beef cattle protein supplements of animal origin—meat scrap, tankage, or fish meal—do not have the special value which they have for swine and poultry. (**907, 922**) It has been shown in Chapter XXIII that these animal by-products can be used satisfactorily for cattle, if they furnish protein more cheaply than do the supplements commonly fed to cattle. However, they had best be mixed with better-liked supplements, for they are often not very palatable to cattle.

1166. Urea as a protein substitute.—Many experiments have been conducted during recent years to study the use of urea as a protein substitute for beef cattle.[14] The most extensive of these investigations are experiments by the Oklahoma Station with fattening calves and with calves, yearlings, 2-year-old steers, and mature cows being wintered.

As is stated in the general discussion in Chapter V concerning urea, it gives the most satisfactory results as a substitute for part of the protein when it replaces not more than about one-fourth of the protein in a ration, and when some grain is fed. (**129**) It is usually less effective as a protein substitute when it replaces more of the protein. It generally does not equal an ordinary protein supplement, such as soybean oil meal or cottonseed meal, when used as a substitute for all of the protein supplement, especially when fed without grain, but mixed with molasses or alfalfa meal.

In 6 Oklahoma experiments fattening calves were full-fed on ground corn and Atlas sorghum silage, with 1 lb. per head daily of alfalfa hay and 1 lb. of cottonseed meal or cake or else 1 lb. of pelleted mixed supplement in which urea replaced half of the cottonseed meal

or cake.[15] In these trials urea supplied about 13 per cent of the protein equivalent in the urea-pellets ration. On the average, the ration with the urea pellets produced just as rapid gains as did cottonseed meal or cake, and the selling price of the fat steers was as high.

In contrast with these excellent results with urea, the gains of fattening calves were unsatisfactory when pellets were used in which 85 per cent of the protein equivalent was supplied by urea. Also, pellets in which urea furnished half of the protein equivalent were inferior to cottonseed meal pellets as the supplement for heifer calves wintered on mature and weathered native pasture.

Florida experiments show that in a ration containing no grain, urea is not a perfect substitute for part of the protein supplement usually fed.[16] In 4 trials fattening steers fed hay, dried citrus pulp, molasses, and cottonseed meal gained an average of 2.28 lbs. a day and required 433 lbs. total digestible nutrients per 100 lbs. gain. When urea replaced 40 per cent of the cottonseed meal, the daily gain was 2.18 lbs., and 456 lbs. total digestible nutrients were needed per 100 lbs. gain.

1167. Mixed protein supplements.—Some protein supplements, especially soybean oil meal or peanut oil meal, give excellent results when used as the only protein supplement for fattening cattle or for cattle being carried through the winter. This is because they furnish protein of good quality.

On the other hand, it has been shown previously that corn gluten meal or cottonseed meal is generally of lower value than linseed meal, when either is used for fattening cattle as the only protein supplement to such a ration as corn grain, corn silage, and hay. (**715, 831**) However, a mixture of one-half cottonseed meal and one-half linseed meal is fully equal to linseed meal. (**832**)

Other combinations of protein supplements that have given excellent results for fattening cattle are [17]: (1) One-third each of cottonseed meal, corn gluten meal, and linseed meal; (2) one-third each of cottonseed meal, linseed meal, and either soybean oil meal or ground soybeans; (3) one-fourth each of cottonseed meal, linseed meal, corn gluten meal, and soybean oil meal or ground soybeans.

There is apparently more advantage in using such a mixture of protein supplements for fattening cattle which are full-fed on grain and which consequently eat relatively little roughage, than for cattle being wintered on roughage plus a small amount of protein supplement. Thus, in Nebraska trials with beef calves being wintered on prairie hay, there was no advantage in using a mixture of soybean oil meal, cottonseed meal, and linseed meal as the supplement, instead of the single supplements.[18] The results were similar in an Oklahoma trial with steers being wintered on native grass pasture.[19]

In metabolism experiments with steers at the Oklahoma Station the protein of a mixture of soybean oil meal, cottonseed meal, and peanut oil meal, used as the supplement to prairie hay, was not significantly better than the protein of the single supplements.[20]

Even with very poor late-cut grass hay as the only roughage for fattening cattle in Ohio trials, soybean oil meal gave as good results as a mixture of soybean oil meal and meat scrap.[21]

In later articles the use is discussed of complex mixed supplements containing not only a protein supplement, but also such ingredients as alfalfa meal, molasses, vitamin supplements, and minerals, including trace minerals. (**1178**) Some of these mixed supplements are much lower in percentage of protein than the common oil meals.

1168. Mineral requirements.—Beef cattle should always be supplied with salt regularly, except in the few areas where the forage or water contains an unusual amount. (**140**) Whether or not there will be any benefit from the use of a calcium or phosphorus supplement will depend entirely on the amounts of these minerals in the particular ration, as is shown later. The amounts of calcium and phosphorus advised per head daily for the various classes of beef cattle are

stated in the revised Morrison feeding standards. (Appendix Table III.)

Wherever there is trouble from goiter, or "big neck," in calves at birth, iodized salt should be supplied the breeding cows, at least during the latter part of the pregnancy period. (**170**) In areas where there is a deficiency of one or more of the trace minerals—cobalt, copper, or iron—the lack should be corrected by the use of a special mineral supplement, or by using trace-mineralized salt instead of common salt. (**172–181**)

There is no need of adding to the usual rations for beef cattle any other minerals, such as sulfur, potassium, or dirt.[22] Also, the addition of kelp to usual rations is not beneficial. (**977**)

1169. Salt.—Beef cattle should receive salt regularly, and the best method is to provide it where they can take what they wish, instead of salting them only once or twice a week.

The need by cattle for salt (sodium chloride) is commonly to furnish additional sodium.[23] Any ordinary ration apparently supplies enough chlorine.

Studies of the salt requirements for beef cattle have recently been conducted by the Kansas Station, with the aid of the Salt Producers Association.[24] These experiments show that cattle being wintered mostly on roughage are evidently benefited much more by supplying salt, than are fattening cattle full-fed on grain and eating much less roughage.

In 3 trials beef calves wintered on roughage and a small amount of protein supplement, with no salt supplied, gained an average of 40 lbs. per head less than did others receiving salt. The addition of salt slightly increased the digestibility of the ration and produced much cheaper gains. In contrast with these results, in 3 trials fattening calves full-fed grain and furnished no salt, gained about as rapidly as others supplied salt.

It is not advisable to mix salt with the concentrates for beef cattle, instead of allowing them to take as much as they desire. In an Arizona experiment fattening cattle allowed access to salt gained 2.58 lbs. per head daily, while others gained only 2.30 lbs. when a supposedly proper amount of salt was included in the concentrate mixture.[24a]

For feeding where the salt is not exposed to the weather, loose salt, block salt, and rock salt are all satisfactory. Loose salt is not desirable for feeding in the open, because of the great loss through weathering. Cattle prefer the softer kinds of block salt to that which is very hard, and they usually eat somewhat more salt when fed loose salt than when supplied with block salt.

In Iowa experiments over several years, cattle fattened in dry lot with shelter ate an average of about two-thirds pound of block salt per head per month.[25] Where salt is in the open, about twice this amount must be supplied, to allow for wastage. In these tests the results were equally good from feeding block salt and loose salt.

Cattle on pasture consume much more salt than those fed in dry lot, and they eat more in spring and early summer, when the forage is abundant and succulent, than later in the season. In a Kansas test yearling and 2-year-old steers on pasture consumed about 2.8 lbs. of block salt per head in July, 1.8 lbs. in August, and 1.2 lbs. in September and October.[26] Nearly equal amounts were lost by weathering of the salt blocks. In another Kansas test, when a salt mixture was fed which was advertised as repelling flies from cattle, no such effect was noted.[27]

Under range conditions a total of about 20 to 30 lbs. of salt is usually provided for each cow during the year.[28] The salt allowance should be from 2.0 to 2.5 lbs. per head a month, when the feed is succulent or when the cattle are subsisting largely on browse. Later in the season, 1.0 to 1.5 lbs. per month are usually sufficient.

1170. Self-feeding a mixture of protein supplement and salt.—In order to save labor, instead of feeding a protein supplement each day to beef cattle on range or pasture, a mixture of the protein supplement and salt is often self-fed. The proportion of salt is adjusted so the

cattle will eat the desired amount of protein supplement a day. (142)

As is pointed out in Chapter V, it is essential in this method that the cattle have access to plenty of water, conveniently available, so that they can get rid of the excess salt in the urine. Otherwise, there may be injury or even death loss. Beef cows have consumed a surprising amount of salt (over 2 lbs. per head daily) for long periods without injury, if they were able to get plenty of water.

Several studies have been made of this method.[29] Usually, the feed cost will be higher than when the proper amount of protein supplement is fed once a day, or when double the amount is fed every other day, and the gain in weight may not be quite so good. The saving in labor may fully offset these factors.

In beginning to use this method, at first the cattle should be hand-fed a mixture of 1 part of salt to 5 or 6 lbs. of protein supplement. Then the proportion of salt should be increased until they will eat no more than the desired amount of protein supplement. A larger proportion of salt is needed with older cattle than with calves. Usually about 1 part of salt to 3 parts of protein supplement will limit the daily consumption of the supplement to 2 lbs., and 1 part of salt to 2 lbs. of supplement will reduce the amount of supplement to 1 lb. a day.

Recent tests indicate that gypsum, instead of salt, may be mixed with the protein supplement, to control the amount eaten.

1171. Calcium.—When legume hay or other legume forage forms any considerable part of the roughage for beef cattle, there is no lack of calcium. Consequently, there is no benefit from adding a calcium supplement like ground limestone to such rations.[30]

If little or no legume roughage is fed, there is much more apt to be a deficiency of calcium for fattening cattle than for breeding cows or young stock which are being wintered chiefly on roughage. This is because all the grains are much lower in calcium than even non-legume hay, fodder, or silage. Fattening cattle which are fed liberally on grain consequently eat only limited amounts of roughage. They therefore get much less calcium than do cattle being wintered mostly on roughage.

Extensive experiments at the Kansas Station and also other trials have proved the importance of adding a calcium supplement to a fattening ration of grain, non-legume roughage, and protein supplement.[31] In these experiments fattening cattle made decidedly smaller and less economical gains on rations of grain, protein supplement, and either sorghum silage or sorghum silage and prairie hay for roughage, than they did when fed a limited amount of alfalfa hay. However, when 0.1 lb. ground limestone or similar calcium supplement was added to the non-legume ration, the gains were nearly as rapid as when alfalfa was fed. The cattle fed the calcium supplement also had stronger bones, required less feed for 100 lbs. gain, and yielded carcasses of higher slaughter grade.

The results of these experiments do not mean that prairie hay or other grass hay was equal to legume hay in value per ton. A much greater amount of protein supplement is, of course, needed to balance the ration when no legume hay is fed.

If fattening calves eat only about 2 lbs. or less of legume hay per head daily, along with a full feed of grain and corn or sorghum silage, plus a protein supplement, it is wise to add 0.05 to 0.10 lb. of calcium supplement to the ration.[32] Such a small amount of legume hay may not provide quite enough calcium for calves, since they need more calcium in their feed than do older cattle.

Whether there will be a benefit from feeding a calcium supplement to beef cows or young cattle that are wintered on non-legume roughage, will depend entirely on the calcium content of the roughage. Unless the forage has been grown on soil very deficient in calcium or unless it is of very poor quality, probably a calcium supplement is not needed.

If the supply of phosphorus in the feed is somewhat below the requirement, adding a calcium supplement when not required may be injurious, instead of

beneficial.[33] When one is in doubt as to whether to use a calcium supplement he should therefore consult his experiment station or county agent. It should be borne in mind that such a phosphorus supplement as bone meal furnishes twice as much calcium as phosphorus.

Limestone and bone meal ground so fine that they were floury gave no better results than coarser products in recent Nebraska and Tennessee studies.[34]

1172. **Phosphorus.**—It has been emphasized in Chapter VI that in many districts of this and other countries the soil and consequently the forage grown on it are so low in phosphorus that severe phosphorus deficiency occurs in cattle. (150–155) In all such areas, if the phosphorus deficiency is not corrected by applying phosphate fertilizer, it is very important to supply a mineral mixture furnishing phosphorus for cattle that are maintained entirely or chiefly on forage.

A decided lack of phosphorus produces the serious results described in Chapter VI. Also, Kansas experiments show that cattle fattened on a phosphorus-deficient ration yield beef which is inferior in palatability and keeping quality, and has a higher shrinkage.[35]

Fattening cattle are much less apt to have an insufficient supply of phosphorus than are beef breeding cattle or young growing cattle. This is because fattening cattle are generally fed a liberal amount of grain. The cereal grains have more phosphorus than most hay, or than corn or sorghum forage. Also, when grown on a soil low in phosphorus, the percentage of the mineral in grain will be fair, though the yield will be reduced. On the other hand, hay, pasturage, and other forage grown on phosphorus-poor soil may be seriously deficient in phosphorus. If a ration for fattening cattle contains, in addition to grain, 1 lb. or more per head daily of cottonseed meal, linseed meal, wheat bran, or other protein supplement that is rich in phosphorus, the ration will generally have enough phosphorus, unless the roughage is low in the mineral.

In most of the experiments with fattening cattle, there has been no benefit from adding a phosphorus supplement to such a ration as corn or other grain, fed with roughage grown on fertile soil, and with or without a protein supplement.[36] In cases where a phosphorus supplement has increased the gains, the improvement has been slight.

When feeds that are low in phosphorus form a considerable part of the ration for fattening cattle, there is apt to be a lack of the mineral. A phosphorus supplement should therefore be supplied when considerable beet pulp, beet molasses, or cane molasses is fed, or when the roughage comes from phosphorus-deficient land.[37]

Whether a phosphorus supplement should be supplied beef cows or young cattle on pasture or range, or being wintered on harvested feeds, will depend entirely on the phosphorus content of the forage. In areas where there is no deficiency of phosphorus in pasture or other forage, there is no benefit from a phosphorus supplement.[38] On the other hand, in phosphorus-deficient areas it is essential that a suitable phosphorus supplement be provided.

Experiments on the King Ranch in Texas show the importance of supplying phosphorus for range cattle in such areas as the Gulf Coast region of Texas, where there is a serious lack of phosphorus.[39] Cows given no phosphorus supplement averaged 200 lbs. lighter in weight than those receiving phosphorus. About half of them showed decided symptoms of phosphorus deficiency. Some became so stiff and "creepy" that they were unable to rise without assistance, and a few died as a result of the deficiency.

Cows supplied with bone meal or given soluble phosphate in the drinking water remained in good condition, a larger percentage had calves each year, and the calves were decidedly heavier and in better condition at weaning time. The results were still better where phosphate fertilizer was applied to the range pasture. Because of the much greater yield of grass, the carrying capacity of this pasture was increased 50 per cent. Also, the calves were heavier at weaning time than in the groups of cattle fed

a phosphorus supplement on unfertilized pasture.

In range areas, phosphorus deficiency is especially apt to occur when cattle must live during a considerable part of the year on mature, weathered grass and other forage, from which the phosphorus has been largely lost by weathering. (361) New Mexico experiments show that there may be a decided benefit from supplying a phosphorus supplement, even when the lack of phosphorus is not serious enough to produce marked symptoms of deficiency.[40] In these tests the percentage calf crop was increased considerably and the weaning weights of the calves were decidedly raised when the range cows were supplied a phosphorus supplement throughout the year, instead of merely during the season when the range forage was mature and dry.

Definite information concerning the minimum phosphorus requirements of the various classes of beef cattle is still very limited. In Idaho experiments it was found that rations for fattening cattle should have 0.18 per cent phosphorus to prevent any deficiency.[41] Such rations supplied about 20 grams (0.044 lb.) of phosphorus daily per 1,000 lbs. live weight. Phosphorus in grain or cottonseed meal was as effective as phosphorus in bone meal in meeting the needs of cattle. (151)

From Wyoming studies it was concluded that heifers raised under range conditions should receive at least 15 grams of phosphorus daily per 1,000 lbs. live weight.[42] An allowance of 17 grams of phosphorus per head daily was sufficient through the first gestation and lactation.

Texas studies indicated that range forage was deficient in phosphorus if it contained less than about 0.16 per cent on the air-dry basis.[43]

1173. Supplying a phosphorus supplement.—When a phosphorus supplement is needed by beef cattle, the best method of supplying it is generally to let them have free access to a suitable phosphorus-rich mineral mixture in a mineral box or trough. Mineral mixtures that are adapted to various conditions are described in Chapter VI. (**186**)

Information is also given in Chapter VI concerning the different phosphorus supplements. (**158–167**) A phosphorus supplement high in fluorine, such as rock phosphate or soft phosphate with colloidal clay (colloidal phosphate), is not safe for continued feeding. (**168–169**)

1174. Trace minerals.—Fortunately, for beef cattle in the greater part of the United States there is no lack of any of the trace minerals. Several experiments have shown that where there is no such deficiency, there is no benefit from supplying trace minerals by using trace-mineralized salt instead of common salt, or by including trace minerals in a mineral mixture.[44]

On the other hand, in an area where there is an actual deficiency of a trace mineral, especially cobalt or copper, the lack must be corrected, as explained in Chapter VI. (**172–175**) Otherwise, the results may be serious.

Also, there may be a benefit from supplying beef cattle with trace minerals if the only roughage they get is of very poor quality, such as late-cut, mature hay or else straw, or if such a feed as ground corn cobs is used instead of hay and silage.[45] It is therefore wise to supply trace minerals in such cases, even in areas where there are no trace mineral deficiencies when cattle have good roughage.

The need for a trace mineral supplement is therefore distinctly an area or an individual problem. Anyone in doubt as to whether there will be an advantage from using such a supplement should therefore secure *impartial* advice from his agricultural college, experiment station, or county agent.

1175. Vitamin requirements.—The only vitamin that is important for beef cattle under usual conditions is vitamin A. This is discussed in detail in the following article.

Even when beef cattle receive no feeds containing appreciable amounts of vitamin D, they are generally protected against any lack because they are commonly outdoors most of the daytime throughout the year. (**201**)

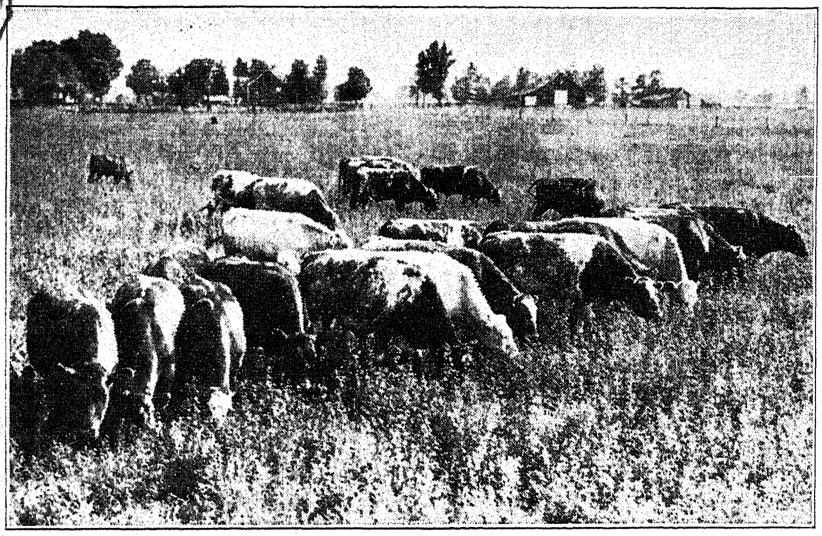
Vitamin D deficiency may occur if beef calves being fitted for show are kept in the stable during the day and are supplied with all the concentrate mixture they will eat, and in addition with all the milk they will take, by means of nurse cows.[46] They then consume but little hay. In such cases, it is advisable to include a vitamin D supplement in the concentrate mixture. (1118)

There is generally no deficiency of vitamin E in beef cattle kept under good practical conditions. However, "white muscle" disease, or muscular dystrophy, of beef calves is a serious problem in a few western range herds.[47] This disease is similar in symptoms to the fatal results of feeding calves a ration devoid of vitamin E. The muscular dystrophy, or degeneration, commonly affects the heart chiefly, and the calf dies suddenly. It differs in this respect from the "stiff lamb" disease, described in Chapter XXXI.

The trouble seems to be more apt to occur in herds where the cows have been wintered on roughage of very poor quality, and subsides when the cows are turned on good pasture. Although the trouble has not been prevented in some cases by a vitamin E supplement, it would seem wise to use the same methods of prevention that are effective in the case of the "stiff lamb" disease.

So far as is known, there is no lack of the other vitamins in feeding beef cattle. (208, 221)

1176. Carotene and vitamin A.—The vitamin A requirements of cattle are commonly expressed in terms of carotene, because cattle get the vitamin from this plant source under all usual conditions. (193) In their report on "Recommended Nutrient Allowances for Beef Cattle," a special committee of the National Research Council recommends an allowance of 5.5 milligrams of carotene daily per 100 lbs. live weight for growth and reproduction.[1] It is believed that approximately this amount is needed to build up and maintain a safe reserve of vitamin A in the body, and for successful reproduction, though considerably smaller amounts have permitted normal growth and reproduction of cattle in various



GOOD PASTURE SUPPLIES AN ABUNDANCE OF CAROTENE

Cattle on good pasture have such an abundant supply of carotene that they are able to store considerable vitamin A and carotene in their bodies. Legume pasture, such as this, is also very rich in protein and calcium.

experiments.[48] For cows nursing calves, a more liberal allowance is recommended, to ensure a satisfactory vitamin A content in the milk.

Beef cattle will receive plenty of carotene when they are on green pasture or when they are fed a reasonable amount of well-cured hay, corn or sorghum fodder, or silage.[49] On the other hand, they may suffer from severe deficiency, if they are maintained for a considerable part of the year on mature, weathered range forage, or if they are fed only such roughage as cottonseed hulls, straw, or hay or fodder of poor quality.

Fortunately, when cattle are on good pasture or are fed plenty of carotene-rich harvested roughage, they store considerable vitamin A and carotene in their bodies. This store is drawn upon, if the supply in the feed becomes inadequate. The length of time cattle can be fed a carotene-poor ration without showing symptoms of vitamin A deficiency will depend on their body store and their age. Calves suffer from a deficiency sooner than older cattle.

In Texas experiments when calves that had been on range pasture were fed a carotene-poor ration, some showed symptoms of vitamin A deficiency within 40 days.[50] The first symptom was usually night blindness, though sometimes convulsions occurred first.

Beef cattle should not be fed for a very long period on a ration that does not include sufficient good roughage to meet the carotene requirements. Vitamin A deficiency will usually be prevented if cattle are fed at least 2 lbs. per head daily of good-quality alfalfa or other legume hay, or 5 to 6 lbs. of corn or sweet sorghum silage, along with other roughage. Grain sorghum silage must be fed more liberally, as it generally has less carotene. On the other hand, hay crop silage is especially rich in carotene.

Although beef breeding cows are often wintered in the wheat-growing districts of the West on nothing but straw plus 1 lb. per head daily of protein supplement, such a ration cannot be advised except under emergency conditions. (**622, 1211**) There should also be supplied, if possible, a limited amount of well-cured hay or other roughage high in carotene or a vitamin A supplement, and also a calcium supplement.

Recent experiments show that beef cows which have been on good pasture during the growing season can usually be wintered on carotene-poor rations, without injury to the cows themselves. However, if they calve before they go on green pasture, the calves may suffer seriously from a deficiency of vitamin A, because the milk will have but little of the vitamin. A vitamin A lack is most serious for calves from birth to about 3 months of age.

When a deficiency of vitamin A occurs under range conditions, it is likely to be complicated with lacks of other nutrients. In North Dakota experiments beef cows that had previously been on good pasture had thrifty calves when the cows were fed for as long as 8 months a ration low in carotene, but supplying ample protein, minerals, and energy.[51]

In an Oklahoma experiment beef heifers were fed low carotene rations in dry lot for consecutive years.[52] They grew normally and successfully completed 2 gestation periods. However, their milk had too little vitamin A to protect the calves against deficiency. In the third gestation on the vitamin-poor ration, all of the cows aborted because of the lack of vitamin A and some died.

New Mexico and Florida studies show that beef cows wintered on mature range pasture will not be affected by a lack of vitamin A, so long as there is even a small amount of green feed in the pasture.[53] In case there has been severe drouth during the growing season and the cows consequently have little store of vitamin A, they may need a supplement furnishing the vitamin.

The disastrous results that follow when cattle are forced to live for a long time on mature and weathered grass or similar forage, are shown by California experiments.[54] Under such conditions cows may produce badly deformed calves. These are known locally as "acorn calves," because it was supposed that they resulted from the cows eating too

many acorns. The experiments showed, however, that acorn calves result when the cows are forced to live for too long a time on mature, weathered forage, with its multiple deficiencies.

If fattening cattle are fed for several months on all the grain they will eat, with but little roughage or with poor roughage, they may suffer from vitamin A deficiency unless the grain is yellow corn, which has some vitamin A value. The deficiency may produce generalized swelling, or edema, known as "anasarca."[55] In such cases, feeding good alfalfa hay has brought striking improvement within 1 to 3 weeks.

1177. Importance of good roughage for fattening cattle.—In most rations for cattle good roughage is the chief source of carotene and also of calcium and certain other essentials. It is therefore not surprising that young fattening cattle do not make good gains when they get no good roughage, unless a special supplement is fed that makes good the lacks.

In two Nebraska tests yearlings fed nothing but ground ear corn and cottonseed cake for only 65 days made decidedly less rapid gains than others fed alfalfa hay as roughage.[56] In an Illinois trial cattle fed for 112 days only a mixture of ground oats, wheat, and corn, with cottonseed meal as a protein supplement, gained but 1.63 lbs. per head daily, in comparison with 2.45 lbs. for others fed alfalfa hay in addition.[57]

If the only roughage for growing or fattening cattle is of very poor quality, it is essential for good gains that a special supplement be fed, which makes good the various nutritive deficiencies. Such supplements are discussed in the following article.

1178. Adding alfalfa; complex supplements.—It has been shown earlier in this chapter that in rations for fattening cattle certain combinations of protein supplements are superior to such a single supplement as cottonseed meal or corn gluten meal. (1167) Also, it has been explained in Chapter II that for satisfactory digestion by ruminants of poor roughage, such as ground corn cobs, straw, cottonseed hulls, or even very poor late-cut hay, special supplements must be supplied. (45) The ration must not only be supplemented with protein or another source of nitrogen, but also with minerals, including perhaps trace minerals, and with certain other factors needed by the rumen bacteria.

The addition to the ration of a small amount of high-quality roughage, such as good alfalfa hay or alfalfa meal, will generally increase the gains considerably.

For example, in recent Ohio experiments steers full-fed on corn-and-cob meal, with late-cut, poor-quality timothy hay and a mineral mixture, gained 2.00 lbs. a day when the ration was supplemented with a mixture of soybean oil meal and dehydrated alfalfa.[58] With soybean oil meal as the supplement, others gained only 1.78 lbs. Because the cost of the dehydrated alfalfa was as great as that of the soybean oil meal per ton, the gains were more expensive with the dehydrated alfalfa. In all probability a similar increase in rate of gain could have been obtained by adding a little high-quality alfalfa or other legume hay to the ration.

It is shown in the following chapter that even with corn or sorghum silage as the only roughage for fattening cattle, the gain is usually increased by adding to the ration a little alfalfa hay or dehydrated alfalfa. (1232)

There has been much interest during the past few years in Purdue Supplement A, developed by Beeson and associates at the Indiana Station.[59] This supplement was designed especially for use with low grade roughages, such as ground corn cobs, but also gives excellent results with corn or other silage. (692)

The revised Purdue Supplement A contains, per 1,000 lbs.: Soybean oil meal, 650.5 lbs.; cane molasses, 140 lbs.; high-grade dehydrated alfalfa meal, 140 lbs.; bone meal, 52 lbs.; cobaltized salt, 17.0 lbs.; and vitamin A and D concentrate, 0.5 lb. In a previous formula molasses feed, containing molasses and a low-grade absorbent, was used instead of the dehydrated alfalfa and molasses.

Feeding 3.5 lbs. per head daily of Purdue Supplement A has been generally recommended. This supplies about 2.5 lbs. of soybean oil meal. While this amount of protein supplement may be needed by fattening cattle fed ground cobs for roughage, it is more than is necessary with corn or sorghum silage as the roughage. Also, with good roughage there is no need of a vitamin supplement.

Several experiments have been conducted to compare Purdue Supplement A or similar complex supplements with soybean oil meal or other simple supplements, in rations for fattening cattle fed roughage of ordinary good quality.[60] In most of the experiments the complex supplements, fed with such roughage, have produced no better gains than the simpler supplements, and the feed cost per 100 lbs. gain has been higher.

Various other complex supplements have been recommended for fattening cattle. For example, the "all-purpose" supplement was very satisfactory for beef cattle and also for other stock in Ohio trials. This supplement is a mixture of 30 lbs. meat scrap, 30 lbs. soybean oil meal, 20 lbs. cottonseed meal, 15 lbs. linseed meal, and 5 lbs. minerals (equal parts by weight of steamed bone meal, ground limestone, and salt.)[61]

A supplement for fattening cattle recommended by Burroughs of the Iowa Station has the following formula per ton: Soybean oil meal, 830 lbs.; cane molasses, 450 lbs.; dehydrated alfalfa, 450 lbs.; urea feed, 100 lbs.; dicalcium phosphate, 60 lbs.; stilbestrol premix, 10 lbs.; and dried torula yeast, 100 lbs.[62]

Whether it is advisable to use a complex supplement for beef cattle instead of an ordinary protein supplement, should depend on the quality of the roughage, and on the cost per ton of the supplement in comparison with such a supplement as soybean oil meal, linseed meal, or cottonseed meal.

1179. Percentage of protein in supplements; feeding every other day.—Many of the formula beef cattle supplements, or commercial mixed supplements, have much less protein than there is in soybean oil meal, cottonseed meal, or linseed meal. In addition to the common high-protein feeds, these contain feeds lower in protein, especially grain, molasses, and alfalfa meal. Some also have mineral and vitamin supplements.

The question therefore arises as to whether such a supplement, having 30 to 20 per cent protein or less, will be as economical as a supplement which has 40 per cent protein or more. The answer will depend, first of all, on whether the deficiency in the feed the cattle get is primarily a lack of protein, or whether they need additional energy about as much as they need more protein. Also, as has been pointed out previously, if they already have plenty of vitamins, a vitamin supplement is not beneficial.

The lower protein supplements may cost less per ton than an oil meal having 40 per cent protein or more, but the cost per pound of protein is much greater. If the lower protein supplement is made of only high-grade feeds, it may furnish about as much net energy per pound as an oil meal.

For wintering young beef cattle or beef cows, 1 lb. of a high-protein supplement, such as soybean oil meal, generally supplies enough protein to produce good results, when the cattle are fed good grass hay or corn or sorghum silage. Since the lack in such roughage is primarily a deficiency of protein, it will take correspondingly more of a supplement having only 20 to 30 per cent protein, to produce equal results.

To supplement mature and weathered native range pasture for young cattle, additional energy may be needed, as well as more protein. It may therefore be profitable to supply more than 1 lb. per head daily of supplement.

The Oklahoma Station has carried on several experiments to compare supplements having 40, 30, and 20 per cent of protein as the supplement to prairie hay or to native range, for wintering heifer calves and bred yearling heifers.[63] All supplements were fed in pelleted form.

The 40 per cent protein pellets were pelleted cottonseed meal. The

lower protein pellets were made of mixtures of cottonseed meal and ground corn. In addition, the lower protein pellets fed certain lots of the bred heifers also contained mineral and vitamin supplements. All the cattle had access to a mineral mixture of 2 parts salt and 1 part bone meal.

Calves fed 1 lb. per head daily of the 40 per cent protein pellets with prairie hay gained much more in winter than did those fed the lower protein pellets, but considerable of the difference was made up by their smaller gains on range pasture the following summer. At the end of the pasture season, their total gain averaged 40 lbs. more than for those fed the 20 per cent protein pellets in winter, and 17 lbs. more than for those fed the 30 per cent protein pellets.

The difference in results from the 40 per cent and the 20 per cent protein pellets was much less for the calves fed 1 or 2 lbs. a day of pellets as the supplement to winter range. Here there was a lack not only of protein, but also of energy.

Similar results were secured with the bred heifers fed 2.5 lbs. of 40 per cent or 20 per cent protein pellets as the supplement to winter range. At the end of the following summer, the weaning weights of the calves from the heifers fed the 40 per cent protein pellets in winter averaged only 7 lbs. more than of the calves from the heifers fed the 20 per cent protein pellets in winter, and the cost of winter feed was $2.16 higher.

There was only a very slight benefit from including mineral and vitamin supplements in the pellets for the bred heifers, and this was offset by the greater cost.

In order to save labor, sometimes beef cattle wintered on the range are fed a double amount of protein supplement every other day, instead of feeding the supplement each day. This does not seem advisable unless there is a great shortage of labor. It would seem that the method would be preferable of restricting the amount of protein supplement by self-feeding a suitable mixture of protein supplement and salt. (**1170**)

In 2 Kansas experiments yearling steers wintered on the range and fed a double amount of protein supplement every other day gained only about half as much as did others fed the protein supplement each day.[64] The effect of delayed feeding of a protein supplement has been discussed in Chapter V. (**116**)

1180. Addition of fat.—It has been mentioned in Chapter XXIII that recently there has been a surplus in this country of low-grade animal fats, largely because of the wide use of detergents instead of soaps. Because of this, the price of such tallows and greases has fallen so much that a small percentage has been added to some formula feeds, or commercial mixed feeds. (**914**) These low-grade animal fats usually sell at a much lower price than plant oils, such as corn oil or cottonseed oil.

In Texas trials adding 5 per cent of cottonseed oil to ordinary fattening rations did not increase the gain, but did reduce the amount of feed required per 100 lbs. gain.[65] Each pound of added fat saved 4 lbs. of other feed.

Adding 5 per cent of raw ground beef tallow to a fattening ration increased the rate of gain in Florida experiments, and increased the feed efficiency.[66] When 10 per cent of the tallow was added to the ration, the gain was reduced.

In Nebraska trials an ordinary ration of ground corn, soybean oil meal, and hay was compared with one in which corn-and-cob meal and hay were fed with pellets made of a mixture of 5.5 per cent beef tallow or corn oil and 68 per cent ground corn cobs, together with cane molasses, soybean oil meal, urea, and bone meal.[67] The ordinary ration produced slightly more rapid gains. With the tallow at 9 cents per pound and ground corn cobs at $16 a ton, in comparison with ground corn at $60 a ton, the gain was slightly cheaper with the pellets.

Animal fat added to a ration should be stabilized with an antioxidant. (**914**)

1181. Water.—It is important that beef cattle have an abundant supply of good water at all times. During winter in the northern states, water in tanks or

troughs should be kept from freezing by using suitable heaters, but there is no need otherwise of warming the water.[68] Separate water troughs should be provided for pigs running with the steers. While it is best to have water before beef cattle at all times, they readily adapt themselves to taking a fill once daily.

The water provision should be not less than 10 gallons per head daily for 2-year-old steers or breeding cows. In Ohio tests fattening calves drank 6.5 to 8.0 gallons of water per head daily.[69] The average daily water consumption of range cows in Arizona was 6.3 gallons, with a minimum of 2.6 gallons in winter and a maximum of 11.5 gallons in summer.[70]

1182. Antibiotic feed supplements; surfactants; tranquilizers; Tapazole.—Numerous experiments have been conducted during the past few years to determine the effect of adding an antibiotic feed supplement to the rations for beef cattle, especially fattening cattle.[71] Unfortunately, the results with the addition of various antibiotics, has varied considerably. This variation is not surprising when one considers the difference in rations, feedlot conditions, and disease levels which confounded the tests. In most of the carefully conduced experiments under good management conditions, little or no response has usually been secured. Indeed, in certain trials the addition actually has been detrimental. In Illinois, Kentucky, and Oklahoma experiments the digestibility of a ration for steers was reduced by adding an antibiotic.

The general acceptance of antibiotics in many large commercial feedlots supports the viewpoint that under such conditions, their use often increases performance. Levels which are commonly recommended for reduction of disease, less scouring, and improved feed efficiency and gain are approximately 10 milligrams per 100 pounds liveweight, with most commercial rations mixed for this purpose furnishing average feeder cattle from 50 to 100 milligrams per head per day of either aureomycin or terramycin. Less than 50 milligrams per head daily is not recommended.

Feeding such antibiotics has also reduced the incidence of bloat, liver abscesses, and foot rot under practical feedlot conditions. It should be stressed however, that antibiotics may not promote any response under many conditions of good management.

The use of high levels of either aureomycin or terramycin for a short period of time in feeder calf rations upon receipt in the yard may reduce the incidence and losses from the shipping fever complex.

Little information is yet available concerning the effect of adding surfactants to beef cattle rations. In a Maryland trial, such an addition was not beneficial with fattening steers. A new "chemobiotic," (tetra alkylammonium stearate) has given variable results. In work at Purdue and Iowa no response was secured, while at Montana and Washington, increases in both gain and feed efficiency were noted. Likely, the differences can be explained by the characteristics of the rations employed.

Tranquilizers, compounds capable of producing increased gain without sedation are now currently being tested. Many different types are under evaluation, and hydroxyzine (Tran-Q) has been approved for use in animal feeds at a level of 2.5 milligrams per head per day. In certain trials, the use of this compound in conjunction with stilbestrol has increased both gains and feed efficiency. The effect was apparently additive to that secured with stilbestrol and antibiotics.

Injectable tranquilizers may be used to quiet cattle at time of shipment to reduce shrinkage, and lessen losses from shipping fever, under the direction of a qualified veterinarian.

Tapazole (1-methyl, 2-mercaptoimidazole), a new compound not yet thoroughly tested or approved for use by the Food and Drug Administration, is reported as stimulating gains, improving feed efficiency, and increasing carcass quality. The levels used varied from 300 to 600 mg. per head daily. Apparently gains are stimulated only for a short period, with the effect tending to wear off.

1183. Stilbestrol; other hormones.—Although earlier results with implanting or injecting stilbestrol (diethylstilbestrol) or other sex hormones gave poor results,[74] present research shows little difference between oral administration of 10 mg. daily per head or implanting diethylstilbestrol at a level of 24 to 36 mg. per head once.

Early tests were often conducted using high levels which resulted in undesirable side effects, although promoting daily gain. Such side effects: elevated tail head, sagging of the loin, mounting of other cattle, mammary development, and sometimes in the case of heifers, prolapse of the vagina. Frequently, the grade of the carcass was lowered.

Many hundreds of trials [76, 77] have been conducted since Iowa [75] reported that 10 mg. daily of stilbestrol per head in the feed would promote increased gains and feed efficiency with little or none of the undesirable side effects previously produced by implantation.

A combination of estrogens, estradiol and progesterone (Synovex) administered at the recommended levels by injection apparently gives the same results as oral or implanted stilbestrol.

Varying effects secured by the administration of hormones are often explained by the fact that certain roughages contain small amounts of estrogenic-like compounds, lessening the response secured, and occasionally leading to undesirable side effects.

Recent Iowa tests indicate a certain calorie-protein ratio is optimum for best carcass quality with steers receiving stilbestrol. Also, increasing the oral dosage during the last 56 days of the feeding period (146 days) increased gains as compared to feeding 10 mg. thruout.

Combinations of silbestrol and testosterone implants were superior, especially with heifers, to stilbestrol alone in Colorado and Ohio trials.

The distribution of stilbestrol containing "premixes" is limited to manufacturers holding effective permits from the Federal Food and Drug Administration. (**964**)

In an Indiana experiment the feeding of a thyroprotein supplement to fattening heifers decreased the gain and the feed efficiency, and in an Oklahoma trial the addition of thyroprotein to a ration for beef cows nursing calves was not advantageous.[78]

1184. Amount of concentrates for fattening cattle.—One of the most important problems in beef production is deciding how much grain or other concentrates to use in fattening cattle for market. The financial outcome depends largely on a wise decision concerning this problem.

Many experiments have been conducted to determine the most profitable amounts of grain to feed fattening cattle of the various ages and under different conditions. These experiments have shown that when full use is made of high-quality roughage, including improved pasture, cattle can be fattened sufficiently to yield desirable carcasses with much less grain than was formerly believed necessary.

The various methods of beef production are discussed in some detail in the following chapter. It is there emphasized that local conditions will determine what method will be most profitable. In baby beef production calves of high quality are full-fed grain in dry lot after weaning and are marketed when thoroughly fat at 18 months of age or less. The calves may be farm raised or may be purchased from the western range. In the former case, the calves are often fed grain in a creep previous to weaning. Baby beef production requires a maximum amount of grain and other concentrates and does not utilize a large amount of pasture and harvested roughage.

At the other extreme is the method in which calves are wintered chiefly or entirely on roughage, pastured the following season without grain feeding, wintered on roughage again, and pastured without grain the second summer. At the close of the pasture season the cattle, then over 2 years of age, are generally fed a liberal amount of grain for 2 to 3 months, to get them fat enough to sell well. If the market does not pay a sufficient premium for grain-fed cattle, they

may be marketed direct from pasture, without receiving any grain. In this method maximum use is made of pasture, hay, and silage, and only a minimum amount of grain is needed.

1185. Fattening cattle on a minimum amount of grain.—In early years corn and other grains were usually so cheap that fattening cattle were generally fed all the grain they would eat, after they were safely on full feed. Two-year-old steers fattened in dry lot were fed an average of over 20 lbs. corn per head daily in addition to hay and other dry roughage.

Later, when corn silage came into wide use for fattening cattle, it was found that when cattle are fed all the well-eared corn silage they will clean up, they will not eat so much corn grain in addition to the roughage. The table in a later article shows the amount of grain and other feeds eaten by cattle of various ages when full-fed grain, along with corn silage, good hay, and a protein supplement. (**1195**)

As the price of corn and other grain became higher in comparison with the cost of hay and silage, several experiments were conducted to find whether 2-year-olds or yearlings can be made fat enough for the large markets when fed only corn or sorghum silage, hay, and 2 or 3 lbs. a day of protein supplement. The following table presents the results of 16 such tests, in each of which one lo of 2-year-old steers, averaging 979 lb in weight, was fed for an average of 1 days only well-eared corn silage, leg or mixed hay, and a limited amount of protein supplement, while another lot received a full feed of corn grain in addition.[79]

CATTLE ON A FULL FEED OF GRAIN

In the corn belt it is usually most profitable to feed fattening cattle a liberal amount of corn or other grain.

The steers fed no corn grain except that in the well-eared corn silage made the surprisingly good average daily gain of 2.1 lbs. per head. Before the introduction of the silo and the use of modern, well-balanced rations this would have been considered a good rate of gain on a liberal feed of grain. However, the steers full-fed corn made considerably more rapid gains, averaging 2.6 lbs. a day. As a result, they were much better

finished at the end of the fattening periods than the steers fed no corn grain except that in the silage.

Feeding no grain except that in corn silage

	Lot I No corn except in silage	Lot II Full-fed corn grain
Average ration		
Corn grain, lbs.	...	14.1
Supplement, lbs.	2.9	2.8
Hay, lbs.	3.8	2.9
Corn silage, lbs.	49.2	27.6
Average daily gain, lbs.	2.1	2.6
Feed per 100 lbs. gain		
Corn grain, lbs.	...	542
Supplement, lbs.	142	110
Hay, lbs.	199	117
Corn silage, lbs.	2,427	1,091
Feed cost per 100 lbs. gain	$14.25	$16.18
Selling price per 100 lbs.	$10.47	$11.17
Net return per head	$—0.03	$2.55

Some of these tests were carried on when corn was high in price, while others were conducted when corn was cheap. The feed costs per 100 lbs. gain accordingly varied widely in the individual trials. The cost with local prices for feeds at any time can readily be estimated from the data in the table. On the average, the feed cost per 100 lbs. gain in these trials was $1.93 higher for the steers full-fed on corn.

Other factors are fully as important as the cost of the gains in deciding the financial outcome. Much more pork is produced by pigs following full-fed steers than when no shelled corn is fed the cattle. Furthermore, full-fed steers reach a better finish and hence bring a higher price on the market. There was not, however, as much difference in the actual selling price in these trials as many experienced cattlemen would predict. In fact, the "no-corn" steers brought only 70 cents less per hundredweight than the others.

Because of the higher selling price and the greater pork credit, the full-fed steers made a much better net return than those fed no corn except that in the silage. However, in some of the experiments conducted when corn was extremely high in price, the cost of gains was so much lower for the no-corn cattle that they returned the greater profit. In other similar experiments with yearling or 2-year-old cattle, the results have generally been like those here summarized.[80]

Experiments have shown that unless grain is extremely high in price in comparison with roughages, it is practically always more profitable to give calves a liberal amount of grain during the entire fattening period.[81]

It has been shown in Chapter XV that when hay-crop silage is fed in place of corn silage, or when cattle are fed hay as the only roughage, considerable grain must be fed to produce as good gains and finish as are secured on corn silage, without additional grain. (439) This is because hay-crop silage and hay have less net energy, on the dry basis, than well-eared corn silage with its considerable proportion of corn grain.

In the alfalfa districts of the West where alfalfa hay is often very cheap in comparison with grain, and less premium may be paid for well-fattened cattle, it may be profitable to feed yearlings and 2-year-olds chiefly alfalfa hay, with but little grain. (1187)

1186. Feeding limited amounts of concentrates.—In fattening 2-year-olds or yearlings it may often be most economical to follow a middle course between full-feeding of grain and supplying no grain except that in the silage. One method is to feed only a limited amount of grain during the entire fattening period. Another method is to feed only roughage and a protein supplement for a time, and then add a liberal amount of grain during a finishing period of 40 to 60 days.

Experiments have shown that the latter method is usually preferable.[82] It generally takes less grain than when a half allowance of grain is fed throughout the entire fattening period. Yet, it produces fully as large gains and as good finish.

The results from giving 2-year-old steers a half feed of corn throughout the

fattening period, in comparison with full-feeding corn, are shown by 11 experiments.[83] Cattle full-fed corn for 131 days ate an average of 13.8 lbs. corn, 28.5 lbs. corn silage, 2.4 lbs. hay, and 2.6 lbs. protein supplement, and gained 2.7 lbs. per head daily. Others fed a half allowance of corn gained 2.3 lbs. on a ration of 6.9 lbs. corn, 41.0 lbs. silage, 2.7 lbs. hay, and 2.5 lbs. supplement.

The feed cost of 100 lbs. gain was 67 cents less for the steers getting the half feed of corn and they sold for only 44 cents less per hundredweight. However, the difference in selling price and the difference in the amount of pork produced by the pigs following the steers more than offset the cheaper gains, and the full-fed steers returned $3.35 more profit per head on the average.

Whether or not to limit the amount of grain for cattle being fattened in dry lot should depend on several factors. These include: the relative cost of grain and roughage and the amounts of each that are available; the grade or quality of the cattle that are to be fattened; the size of the premium that can probably be secured for well-fattened cattle; and how soon one wishes to have the cattle ready for market. Farmers who plan to fatten cattle mostly on roughage usually buy the plainer type of feeder cattle and those in rather thin condition. They know that they cannot hope to top the market with cattle fed largely on roughage, even if they are of high quality. They therefore buy cheaper cattle and feed them so as to secure low-cost gains.

Several experiments have been conducted recently by western experiment stations to determine the best proportion, or ratio, of concentrates and alfalfa hay or other roughage to feed fattening yearlings or 2-year-olds.[84] These trials show that the most rapid gains are generally secured when 2 or 3 lbs. of concentrates are fed to each pound of hay. Restricting the amount of roughage and thus increasing the proportion of grain and other concentrates beyond this level, tends to decrease the gain instead of increasing it. Still more important, such a high proportion of concentrates considerably increases the cost per 100 lbs. gain.

Feeding a smaller proportion of concentrates than 2 lbs. per pound of hay, reduces the gain and the cattle do not reach a good degree of finish. If it is desired to reduce the amount of grain fed, it is best to feed but little grain during the first month of the fattening period and then gradually increase it until the cattle get a liberal amount.

1187. Fattening cattle on alfalfa hay. Some years ago, cattle in certain of the western range districts were often fattened on only alfalfa hay, or on alfalfa hay and other roughage. Though young cattle cannot be made really fat on roughage alone, this method was economical because the local markets did not pay much premium for well-fattened cattle.

During recent years, few cattle have been fattened on alfalfa hay alone, because there has been a greater demand for beef from grain-fed cattle. However, in the western range areas, fattening cattle are even now often fed a considerably smaller amount of grain than are cattle fattened in the corn belt and eastward. This is because alfalfa hay is commonly cheap in comparison with the price of grain. In Arizona and New Mexico trials it was more profitable to feed yearling steers 7 or 8 lbs. of grain per head daily, along with good roughage, than to reduce the allowance to only about 4 lbs.[85]

In 16 tests some years ago, cattle fattened on alfalfa hay alone for periods averaging 110 days were fed 32 lbs. of hay per head daily (including the wastage) and gained only 1.20 lbs. daily.[86] For each 100 lbs. of gain there were required 2,985 lbs. of hay. In 8 of the experiments, adding a limited amount of grain to alfalfa hay increased the average gain 0.45 lb. a day. Each 100 lbs. of grain saved 308 lbs. of hay, without considering the better finish of the grain-fed cattle.

When cattle are fattened on alfalfa hay alone, poor-quality hay should not be chopped or ground in an attempt to reduce the wastage. This will force the cattle to eat the stems or weeds that they could otherwise discard, and is therefore apt to reduce the gains and be a disadvantage, instead of a benefit. The refuse hay can often be used advantageously for breeding cows or stocker cattle that are being wintered. Idaho and Oregon tests show that chopping good-quality alfalfa hay increases its value about

18 per cent for cattle being fattened on hay alone.[87]

Adding corn silage or other silage to alfalfa hay increases the rate of gain fully as much as feeding a limited amount of grain, and often the gains are cheaper than with grain. In 9 trials cattle fed silage and alfalfa hay gained 1.64 lbs. per head daily, while others fed nothing but alfalfa hay gained only 1.12 lbs.[88] Each 100 lbs. of silage actually saved an average of 115 lbs. of alfalfa hay in these tests, and in addition the silage-fed cattle were much better finished.

[illegible]. General Factors Influencing Beef Production

1188. The necessary margin.—Under usual conditions the cost per 100 lbs. of the gains made by feeder cattle fattened for market is greater than the selling price of the finished animals per hundredweight. Therefore, in order to make a profit or even to prevent loss, a higher price per 100 lbs. must be obtained for the fat cattle when marketed than their original cost per 100 lbs. as feeders. This is also generally the case in fattening feeder lambs or older sheep.

The difference between the cost per hundredweight of the feeder animals and their selling price per hundredweight when fattened is called the *margin.* The term *necessary margin* means the margin that is required for any particular lot of animals to avoid loss.

To find the margin that will be needed, the other expenses must be taken into consideration, in addition to the cost of feed for each 100 lbs. of gain. Where full value can be secured from the manure, this and the credit for the pork produced are commonly assumed to cover the cost of labor, housing, taxes, interest, incidental expenses, and the mortality risk. However, one must include in his financial estimates the expenses incident to the purchase of feeder cattle and of bringing them to the feed lot, and also the expenses of marketing them after they are fattened.

The following factors have an influence on the margin that is needed for any particular lot of cattle:

1. The higher the cost of the gains, the greater will be the necessary margin.

2. The more the animal weighs when placed on feed, the less is the necessary margin, because the increased selling price is secured on more pounds of initial weight. This factor will be offset, however, if the heavier cattle are older and make more expensive gains.

3. The higher the initial cost is of the feeder cattle per hundredweight, the smaller is the necessary margin. This is because the initial cost of the animals per 100 lbs. will then more nearly equal the cost of the gain per 100 lbs.

4. The larger the total amount of gain made per head by the cattle, the greater will be the margin needed to prevent loss. This is because the margin on the initial weight of the animal must cover a greater number of pounds of expensive gains.

5. A greater margin is needed when the expenses are heavy for getting the steers to the feed lot and later to the market.

In general, the necessary margin is usually less for fattening calves than for older cattle. This is because they make much cheaper gains, and also because their initial cost per 100 lbs. is commonly higher than for yearlings or 2-year-olds.

The manner in which the necessary margin can be estimated is shown by the following example: Let us suppose that 700-lb. yearling steers cost $22.00 per hundredweight when put in the feed lot. They are to be fed 160 days, and it is expected that they will gain 2.0 lbs. per head daily at a feed cost of $26.00 per 100 lbs. gain. Assuming that the pork produced by pigs following the steers and the value of the manure will offset the labor and miscellaneous expenses, what will be the necessary selling price and the necessary margin, after deducting the marketing expenses?

The steers will make a total gain per head of 320 lbs., and the total feed cost of this gain will be $83.20 at $26.00 for each 100 lbs. gain. Adding this to the total initial cost of the cattle per head, which was $154.00, we will have $237.20 as the total cost per head of the fat cattle. Dividing this total by the final weight of the cattle, which is 1,020 lbs. (700 lbs. plus 320 lbs.), we find that the cattle must bring $23.26 per hundredweight in the feed lot to break even.

To determine the necessary margin, we subtract the initial cost per hundredweight from this necessary selling price. This gives us $1.26 as the necessary margin under these particular conditions.

1189. Value of beef blood for beef production.—Experiments have proved

that "blood tells" in beef production, just as it does in other types of stock farming. Good returns cannot be expected when calves are raised for beef out of scrub or inferior cows, and sired by a scrub bull or one lacking in the desired beef characteristics.

In a survey by the United States Department of Agriculture among farmers in 36 states, it was estimated that purebred beef cattle had an earning power 37 per cent greater than that of common or scrub stock, based on utility alone and not considering the greater pride and pleasure in caring for well-bred cattle.[89] Those who had replaced scrub bulls with purebred sires reported an average increase of 48 per cent in returns due to the use of the purebred sires.

In comparison with scrubs, well-bred beef cattle have the following advantages: (1) They make more rapid gains and are therefore heavier at a given age; (2) the gains are usually cheaper; (3) the animals mature earlier; (4) they furnish a higher percentage of dressed carcass; (5) they produce a greater proportion of the more valuable cuts of meat; (6) their carcasses have less internal fat; and (7) their beef is superior in quality.

Several experiments have shown that well-bred beef cattle make more rapid and cheaper gains than scrubs. In 6 Oklahoma tests, for example, well-bred beef calves from a purebred sire and high-grade beef cows gained 1.97 lbs. a day in comparison with 1.67 lbs. for scrub calves and 1.88 lbs. for calves from purebred bulls and scrub dams.[90] Also, the feed cost per 100 lbs. gain was 10 per cent less for the well-bred calves than for the scrubs, and 4 per cent less than for the calves out of purebred bulls and scrub dams. In considering these results, it should be borne in mind that the scrub cattle were vigorous, thrifty animals and that they were fed and cared for as well as the well-bred beef cattle. Commonly, on farms where scrub animals are raised, the methods of feeding and management are no more improved than are the stock.

In all of the tests comparing well-bred beef calves with scrubs, the chief difference has been in the value of the cattle when marketed. Thus, in the Oklahoma trials the well-bred steers sold for $1.71 more per 100 lbs. than the scrubs, and for 92 cents more than the steers from purebred bulls and scrub cows.

1190. Superior carcasses of well-bred beef cattle.—Well-fattened steers of good beef type have a somewhat higher dressing percentage than scrub or dairy steers that are equally fat. Also, the beef steers have a higher percentage of loins and ribs, which are the most valuable cuts, and a smaller proportion of the cheap cuts. The actual differences in dressing percentage and in percentage of different cuts is not large, however.

There is a more marked difference in the distribution of fat in the body. In the carcass of a well-bred beef steer more of the fat is distributed throughout the muscular tissues, and less is deposited about the internal organs, where its only value is for tallow. Fat distributed throughout the lean meat makes it tender, juicy, and toothsome. On the other hand, when it is deposited in separate masses anywhere about the body, it has but low value.

One of the most important differences between beef cattle and scrub or dairy-bred cattle is in the quality of beef produced. The thick-fleshed cuts from well-fattened beef cattle command a much higher price on discriminating markets than the thin-fleshed cuts from scrubs or dairy animals. Fat cattle of good beef type therefore sell for a considerably higher price on the market and bring a much larger return to the man who has raised them.

1191. Fattening cattle of the various market grades.—For the beef producer who raises the animals he fattens, there is no question but what well-bred animals of the beef breeds are the most profitable. The matter is more complicated for one who fattens feeder cattle that he buys on the market. He must consider not only the cost of the gains he can expect from cattle of the various grade, but also the difference between the initial cost per hundredweight and

the probable selling price when fattened.

Careful experiments have shown that thrifty, well-selected common-grade or medium-grade feeder cattle will make fully as rapid and cheap gains as will good to choice feeders, which are of better beef type and conformation. This is chiefly because the lower grade feeders are generally thinner in flesh than the better cattle. Furthermore, when the cattle are marketed after being fattened, there will usually be considerably less difference in the selling price per hundredweight than there was in their cost as feeders. Consequently, the profit has generally been greater from the medium or common grades than from the better grades.

The results from fattening western feeder steers of various grades are shown by 15 trials, in each of which a group of good or choice feeder steers was fed a good ration in direct comparison with a group of medium feeder steers and also with a group of common steers.[91] The good to choice steers were high-grade beef cattle of good type, averaging 624 lbs. at the start. The medium steers were of the beef breeds, but were of less desirable type and were usually somewhat thinner, averaging 607 lbs. in weight. Many of the common feeders were of dairy breeds or showed some dairy blood. Although they were thrifty, they were thinner than the better grades and averaged only 550 lbs. in weight.

There was practically no difference in the rate of gain made by the various grades of cattle. The best grade averaged 2.31 lbs. a day, the medium feeders, 2.37 lbs., and the common feeders 2.35 lbs. Also, the feed cost per 100 lbs. gain was slightly the lowest for the common feeders, and a trifle lower for the medium feeders than for the good to choice feeders, which carried more flesh at the start. The average dressing percentage, in 5 experiments where this was determined, was only 56.9 per cent for the common feeders, while it was 58.7 per cent for the medium group and 60.6 per cent for the best cattle.

The average initial cost of the good to choice feeders in these tests was $2.34 more per 100 lbs. than for the common feeders, and $1.24 more than for the medium feeders. While the better cattle also sold for higher prices when fat, there was much less difference in the selling price than there was in the initial cost. The good to choice steers sold for only $1.16 more per hundredweight than the common grade, and the medium steers for only 68 cents more than the common cattle.

As a result of their cheaper gains and the greater margin, the net return per head over cost of feed was decidedly greater for the medium and for the common feeders than it was for the cattle of the better grades.

Unless the lower grade steers are well selected and are thrifty and growthy, their gains may be decidedly less rapid and more expensive than those of better-grade cattle. For example, in 3 Georgia experiments good feeders gained 2.42 lbs. per head daily, in comparison with only 1.89 lbs. for common feeders.[92] The feed cost per 100 lbs. gain was 6 per cent less for the good feeders.

1192. Choosing between the grades of feeder steers.—One should not conclude from the previous summary that the best profits are always made from buying the lower grades of feeder cattle. The financial outcome from the various grades will depend primarily on the margin that can be secured between their purchase price as feeders and their selling price as fat cattle.

The spread between the prices for good to choice fat cattle and for those of the lower grades is usually the greatest in summer and fall. This is because there are fewer such cattle then coming on the market. The spread is apt to be smallest in late winter and spring, when a large number of well-fattened cattle are coming to market from the feed lots.

In purchasing feeders one should not base his decision on the spread in price between the various grades of fat cattle at that time, but upon the difference there will probably be, based on average prices, when he has the cattle fattened and ready for market. If one has access to a special market that pays

a large premium for thoroughly fat cattle of high quality, obviously he cannot hope to secure the premium unless he fattens animals of the best grades. On the other hand, if the cattle are to be fattened chiefly on roughage, with but little grain, it will not pay to buy high-grade feeders, because they will not be fat enough to bring a top price when marketed.

In purchasing feeders of the lower grades it is especially important that they be carefully selected and that only thrifty animals be bought. Otherwise, the results may be disappointing. Some experienced feeders specialize in fattening cattle that do not even come up to the common grade. Such animals are in disfavor on the market, for most good stockmen do not want them on their premises. Hence, they can often be bought at a price that offers good possibilities of profit. Many such animals are unthrifty, and hence the death losses are higher than for good cattle. Also, more skill is necessary in feeding these cheap cattle. The fattening of such cattle should therefore be undertaken only by an expert who knows cattle and knows market conditions.

1193. Dairy steers vs. beef steers vs. crossbreds.—The question is often asked as to the value for beef of steers from the dairy breeds, especially Holsteins, in comparison with steers of the beef breeds. Experiments have shown that young dairy-bred steers make fairly good beef when well fattened. However, because of lower quality of carcass, they sell at a considerably less price on the market when fat. They are therefore worth much less per 100 lbs. as feeders than are well-bred beef steers.

In Michigan and Wisconsin trials Holstein steer calves made slightly more rapid gains, on the average, than did beef calves, because the Holsteins were thinner at the start.[93] In the Michigan trials the feed cost per 100 lbs. gain was a trifle higher for the Holsteins, but the reverse was true in the Wisconsin tests. The chief difference was in the selling price, for the Holstein steers brought $2.43 less per hundredweight when fattened than did the beef steers. The dressing percentage was 3.1 per cent lower for the Holsteins than for the beef steers.

In the Wisconsin experiments crossbred Holstein-Angus steer calves were also tested. They made desirable baby beeves, both on foot and when slaughtered, though they were not so smoothly covered with fat as Angus steers. However, their dressing percentage was about as high as for the Angus steers. Steers of the dual-purpose breeds yield better carcasses than dairy steers, but not usually equal to those from steers of the beef breeds.[94]

1194. Relation between conformation and gains.—It is well known that individual cattle of the same breed and age differ greatly in rate and economy of gains. Studies have been conducted to endeavor to find just what points of conformation are important as indications that an animal will make rapid and cheap gains and yield a high-grade carcass when fattened.[95] In these studies feeder cattle have been carefully measured and scored, and then records have been kept of the gains made by the individual animals, of the amounts of feed required per 100 lbs. gain, and of the quality of carcass yielded.

It has been found in most of these studies that the appearance of feeder cattle is not a reliable indication of their capacity to make rapid gains or economical gains. Experienced judges of cattle are generally much more successful in picking out young cattle that will yield high-quality carcasses when fattened, than they are in predicting just which animals will make the largest gains or require the least feed per 100 lbs. gain. They prefer animals that are deep, broad, and compact, with roomy digestive tracts and evidences of strong constitution. Cattle feeders also know that temperament is of great importance in the feed lot. The calm, quiet animal which eats its fill and then lies down is almost sure to outgain an animal that is nervous and restless.

These studies have shown that rate of gain is highly correlated with economy of gain. The cattle which make the most

rapid gains generally require less feed per 100 lbs. gain than do slower-gaining cattle.

In comparisons of large, medium, and small or compact type steers, the large or medium type cattle have usually made more rapid gains than those of small type, but the more compact cattle reach a given slaughter grade at a lighter weight.[96] If fattened to the same grade, there has not been an appreciable difference in the amounts of feed required per 100 lbs. gain. (1209)

Investigations by the United States Department of Agriculture and certain of the experiment stations show that marked improvement can be made in the efficiency of beef production by selecting young bulls on the basis of the rate and efficiency of gain in Record of Performance tests.[97] In this method of testing, bull calves are fed individually, after weaning, on a standard fattening ration, and the gains and feed efficiency accurately determined. An even more reliable basis of selection is by progeny testing, in which the offspring from various sires are similarly tested.[98] However, progeny testing has much more limited practical usefulness.

1195. Influence of age in fattening cattle.—It is well known that young animals require much less feed per pound of gain in weight than do older ones, and that their gains are decidedly cheaper. The reasons for this marked difference have been explained in Chapter IX. (265)

Comparison of calves, yearlings, and 2-year-olds

	Calves	Yearlings	2-year-olds

* Average of 16 experiments.
† Average of 11 experiments.

On account of the great practical importance of the matter, many experiments have been conducted to compare the costs of gains and the net returns from fattening cattle of various ages. The table on this page gives the results secured in 17 experiments in which calves, yearlings, and 2-year-olds were

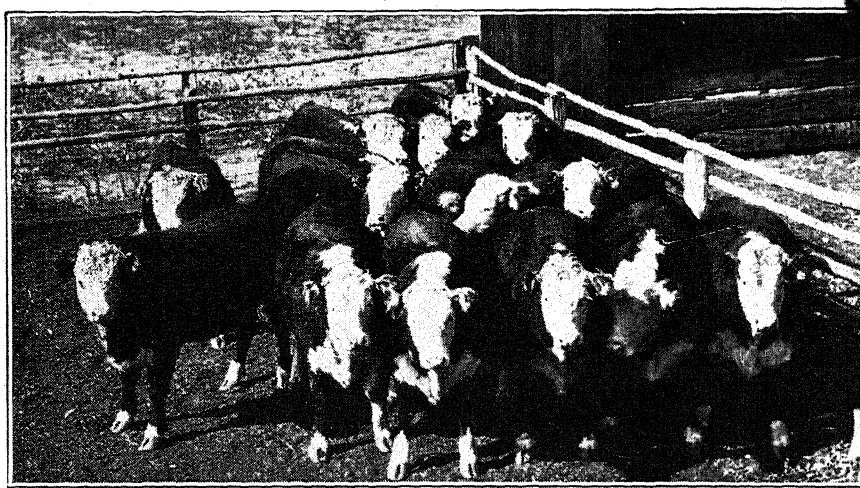
directly compared.[99] In these trials special efforts were made to secure feeder cattle of equal quality for the different ages. Cattle of good beef type and conformation were used in practically all the tests.

The cattle were fed grain (corn in all except one experiment) and legume or mixed hay. In addition they received a small allowance of protein supplement in certain of the tests, and had silage in addition to hay for roughage in 6 of the trials. Similar results have been secured in other experiments which did not include all the ages, or in which somewhat different rations were fed.[100]

An average of 197 days was needed to get the calves fat enough to meet market demands, while only 174 days were required for the yearlings and 162 days for the 2-year-olds. Often it will take 225 days or more to fatten calves properly, if they are thin when put on feed.

When young cattle are fed liberally from calf-hood, the daily gains will reach their maximum during the first year, and then the rate of gain will gradually decline. However, in the case of feeder cattle which are in thin condition when fattening begins, yearlings and 2-year-olds will make slightly more rapid gains than calves.

In these experiments the average daily gains were 2.40 lbs. for the 2-year-olds, 2.26 lbs. for the yearlings, and 2.19 lbs. for the calves. These are somewhat larger gains than are secured, on th average, in commercial cattle feeding, these experiments cattle of good qu were fed excellent rations under car supervision. Therefore, the data in table show the results that can



A FINE BUNCH OF BABY BEEVES

In baby beef production, well-bred beef calves must be fed a liberal amount of grain and a properly balanced ration. (From U.S. Department of Agriculture.)

cured by experienced stockmen and under favorable conditions.

These experiments were conducted when the prices of feeds and of cattle were much lower than now. The financial data in the table therefore merely show the relative feed cost per 100 lbs. gain for the different ages, and the relative cost of the feeder cattle and the relative selling prices.

There was not a great difference in the total gains, though a total of about 40 lbs. more gain was necessary to finish the calves properly than was required for the yearlings or 2-year-olds. Often, the total amount of gain needed to finish calves properly will be somewhat more

than was made by the high-quality calves in these experiments.

The amounts of feed eaten per head daily by the calves were considerably less than for the older cattle. However, since the calves were fed for a longer period, there was much less difference in the total amount of feed consumed by cattle of the different ages.

The economy of the younger cattle is shown by the amounts of feed required per 100 lbs. gain and by the feed cost per 100 lbs. gain. While the feed cost of each 100 lbs. of gain made by the calves was only $9.14, it was $10.98 for the yearlings and $12.07 for the 2-year-olds.

Calves usually cost more per 100 lbs. as feeders than do yearlings or 2-year-olds, and this is shown in these experiments. While the average initial cost of the yearlings and 2-year-olds was approximately the same, the cost of the calves was 57 cents per 100 lbs. higher than for the yearlings.

This greater initial cost of the calves was more than offset by their cheaper gains and by the further fact that they sold for a little higher price per hundredweight than the yearlings or the 2-year-olds. As a result, the average net return over the cost of feed, after allowing credit for the pork produced by the pigs following the cattle, was $9.39 per head for the calves, in comparison with $4.08 for the yearlings and $3.25 for the 2-year-olds.

Three-year-old cattle will usually require even more feed per 100 lbs. gain than 2-year-olds. Old cows generally do not make as rapid gains as yearlings or 2-year-olds, and their gains cost considerably more.[101]

TWO-YEAR-OLD STEERS BEING FATTENED ON PASTURE

Older cattle can be fattened chiefly on good pasture, with a minimum amount of grain.

1196. Which age of feeders should be purchased?—One should not conclude from the preceding summary that it is always more profitable to feed calves than older cattle. Whether or not this will be the case depends on the conditions at any particular time. In deciding which age of feeders to purchase, the following factors are important:

If the cost of yearling or 2-year-old feeders per 100 lbs. is enough below that of calves to offset fully the cheapness of the gains by calves, then the profit may be greater from feeding the older cattle.

Somewhat more care is necessary in

feeding calves than in the case of yearlings or 2-year-olds. Calves are not well suited to utilize roughage of poor quality. Therefore, if one wishes to use considerable corn stover, straw, or low-grade hay, he will prefer older cattle. Also, calves must have a liberal amount of grain to fatten properly, while 2-year-olds will reach a fair market finish on nothing but good corn silage, a little hay, and sufficient protein supplement.

Some people decidedly prefer the beef from well-finished older cattle of good quality to that from baby beeves, as it has more flavor. There is therefore still a definite demand for such carcasses. At certain times the supply is not sufficient to meet this demand, and then the price for fat yearlings or 2-year-olds of choice quality may be higher than that for baby beeves.

Calves have another advantage that is sometimes of importance, in addition to their cheaper gains and higher average selling price per hundredweight when well fattened. They will continue to make good gains for some time after the end of the ordinary feeding period, and if they are not continued on feed too long their carcasses will not be wastefully fat. Therefore, if the prices for fat cattle happen to drop at the time when it has been planned to market them, and one believes the prices will be better a few weeks later, calves can successfully be continued on feed for a reasonable length of time.

On the other hand, when 2-year-olds are already well fattened, further gains are very expensive. Also, the cattle will soon become so fat and heavy that they will not bring a satisfactory price, even if there is improvement in the general level of cattle prices.

1197. Efficiency of gains of cattle of various ages.—The most complete records of the amounts of feed consumed and the gains made by beef cattle from birth to market are those obtained by Haecker at the Minnesota Station.[102] So that all the feed consumed could be accurately determined, the calves were raised by hand, instead of nursing their dams.

During the various periods the steers were allowed all the roughage (corn silage and prairie hay) they would eat, but the amount of concentrates was somewhat smaller than is commonly fed to cattle that are being fattened for market. When the steers reached a weight of 1,200 lbs. they were sufficiently well fleshed for the market. Some were continued on trial until they reached 1,500 lbs. and were very fat.

The daily gains increased until the steers reached 600 lbs. in weight, after which they decreased slightly. The amount of feed required for 100 lbs. gain rose steadily as the steers grew and fattened. While only 225 lbs. total digestible nutrients were needed for 100 lbs. gain between the weights of 100 to 200 lbs., over 800 lbs. total digestible nutrients were required for 100 lbs. of gain after the steers reached 1,000 lbs.

The feed cost of 100 lbs. gain was higher for the first period than for those immediately following, because of the whole milk that was fed. The cost then rose gradually from $4.90 per 100 lbs. gain between 200 and 300 lbs. live weight up to $15.40 between the weights of 1,400 and 1,500 lbs. The feed cost of the gains was especially high after the steers had reached 1,200 lbs.

Though the older steers required more total digestible nutrients per 100 lbs. gain, they actually stored as much energy as did the younger ones for each 100 lbs. of total digestible nutrients they ate. They were therefore as efficient as the younger steers in converting food energy into energy of beef produced. The greater apparent efficiency of the young steers was entirely due to the fact that their gains were high in water and low in fat, while those of the older steers consisted chiefly of energy-rich fat.

In these studies it was found that the 1,200-lb. steers yielded in their carcasses 10.95 lbs. of edible meat and fatty tissues, containing 6.02 lbs. dry matter, for each 100 lbs. total digestible nutrients they had consumed during their growth and fattening. During the entire lives of these steers they converted about 10 per cent of the gross energy in the

feed they ate into the energy stored in their body tissues.[103] Thus, the "over-all" efficiency of the steers was 10 per cent.

1198. Excessive fattening wasteful.—Experienced cattle feeders know that it never pays to carry fattening cattle to an unnecessarily high "finish." After an animal is already well fattened, any further gains are much more expensive. This is because the gains then consist chiefly of fat and contain but little water. Also, after an animal has become fat, its appetite is less hearty, and consequently it eats less feed in proportion to its weight. It therefore has a smaller proportion of its food available for making gains, after the maintenance requirements have been met.

Not only are the gains exceedingly expensive when cattle are carried to extreme fatness, but also the carcasses from such animals do not meet the desires of most consumers. The lean meat will, it is true, be of the highest quality, but too large a proportion of the various cuts will consist of masses of fat which are not usually eaten.

Studies by the United States Department of Agriculture show that if cattle are fattened beyond the slaughter grade of "good," only a relatively small quantity of human food is produced during the additional period of fattening.[104] This is because most of the added gain is in the form of fat which is in excess of what the average person will eat along with the lean meat. It is estimated that to this degree of fatness, each 100 lbs. of grain fed produces about 6 lbs. of nutrients that are consumed directly as human food. In fattening cattle more, each additional 100 lbs. of grain fed produces only about 2 lbs. of added nutrients for humans.

The demand for highly-fattened steers is limited, even on the large central markets, for most consumers cannot afford this wasteful class of beef. Often such steers will bring some premium over those which are fattened only enough to yield desirable carcasses. However, unless one has a special market outlet for highly-fattened cattle, the difference in price is commonly so small that it fails to offset the high cost of carrying the steers to this degree of fatness.

The wise beef producer will therefore keep posted with reference to the market prices of the various grades of cattle and will sell his steers just as soon as they are sufficiently well fleshed to return the most profit. While it would be a source of pride to him to sell a load of steers that would "top the market," he knows that often this reduces rather than increases his net return.

1199. Heifers vs. steers; bulls.—On the large markets in the United States fat beef heifers commonly sell for a lower price than steers of similar quality and condition. However, experiments have proved that when young heifers are properly fattened but are not over-fat, they yield carcasses that are about equal to those from steers.[105] In these experiments there have been no appreciable differences due to sex in the dressing percentage, in the retail value of the carcasses, in the color of the meat, or in its tenderness and palatability when cooked.

Though heifers do not make as rapid gains as steers, they become fat sooner than steers and therefore do not require so long a feeding period. If fed for the length of time needed to finish steers properly, they become wastefully fat. Also, it does not usually pay to get heifers fat enough to reach the "choice" slaughter grade. If properly-finished heifers are sold at weights of not over 650 to 900 lbs., they will generally bring a better price than if fed to a heavier weight.

Heifers should therefore be marketed just as soon as they are fat enough to meet the market demands, which will be 2 to 3 months earlier than in the case of steers of the same age. Their gains will then generally cost no more per 100 lbs. than the gains of steers fed for the longer period.

In 7 experiments in which heifer calves have been fattened for an average of 165 days in comparison with steer calves fed for 239 days, the heifers gained an average of 2.23 lbs. a day and the steers only a trifle more, 2.27 lbs.[106] The average feed cost per 100 lbs. gain was the same for the heifers and the

steers. The initial cost of the heifers was 66 cents per hundredweight less than that of the steers, but the selling price when fattened was $1.36 less than for the steers. In these trials the net return per head was therefore considerably larger for the steers.

In other trials in which heifer calves or yearlings have been fattened for the same length of time as steers, the steers have gained decidedly more.[107] Also, they have required less feed per 100 lbs. gain, because they were not so fat.

Because the selling price of fat heifers is usually 50 cents to $2.00 less per 100 lbs. than for fat steers of equal quality, their initial cost per hundredweight must be decidedly lower, in order to secure as large a net return.

In fattening heifers for market, the practice is often followed of breeding them 3 to 4 months before they are to be marketed. This is done because bred heifers are less active and may require a little less feed per 100 lbs. gain. If heifers are no further advanced in pregnancy than this, there is no appreciable decrease in the value of the carcasses.[108] However, unless a buyer on the market can be certain that none of a particular lot of heifers is farther advanced in pregnancy than this, he must discount the price he offers, in order to be safe.

Spayed heifers are apt to make no better gains than open heifers, even after they have recovered from the effects of the operation.[109]

If possible, heifers should be fed apart from steers, to lessen the disturbance at the heat periods. However, in a Minnesota test about as good results were secured from a mixed lot of heifers and steers as from the two sexes fed separately.[110]

Bull calves fed a fattening ration make more rapid gains than steers or heifers and require less feed per 100 lbs. gain.[111] However, they are not so well fattened when fed for the same length of time, and sell at a decidedly lower price per hundredweight.

1200. Preparation of feeds.—The general principles which determine whether any particular method of feed preparation will prove profitable have been fully discussed in Chapter IV. Information is given in Chapters XX and XXI on whether or not it pays to grind each of the grains for beef cattle.

In general, the small grains should all be ground for beef cattle. In the case of corn, there is usually not enough saving through grinding to warrant the expense, if pigs follow the cattle to utilize any unchewed grain in the droppings. Also, calves chew corn so thoroughly up to 6 or 9 months of age that there is not much saving by grinding it for them.

Statements are sometimes made that rolling or crushing grain is preferable to grinding it. However, in several experiments with fattening cattle there has usually been little or no advantage in rolling or crushing over grinding.[112] Crushed or rolled grain is popular with herdsmen fitting cattle for show or sale, as it is somewhat more bulky than ground grain.

1201. Chopping or grinding dry roughage.—Experiments have shown that it does not generally pay to go to extra expense in chopping good-quality hay for beef cattle, when it is fed so as to avoid undue waste.[113] If hay can be stored in chopped form as cheaply as long hay, then chopping may be desirable. When hay is chopped for cattle, coarse chopping is decidedly preferable to fine chopping.

Chopping coarse-stemmed hay, such as much of the soybean hay, makes more saving than in the case of good alfalfa or clover hay. For example, in a Louisiana test chopping soybean hay for fattening cattle increased its value 25 per cent.[114] Shredding or chopping of corn or sorghum fodder or stover is advisable to lessen the waste, and also because the uneaten portion then makes much better bedding.

It does not generally pay to grind hay or other dry roughage for beef cattle, with the possible exception of sorghum fodder which contains considerable grain. Grinding is much more expensive than chopping, and in several tests has

generally made no more saving than chopping the roughage.[115] Processing sorghum fodder in a roughage mill that cracks the seed increases its value considerably more than merely chopping or shredding it.[116] However, the ground fodder generally has a much lower feeding value per acre than sorghum silage. (354)

In some of the western alfalfa districts where hay is usually cheap, it is commonly fed to fattening cattle in very liberal amounts. The wastage is hence greater than when only as much is supplied as will be cleaned up reasonably well. Chopped alfalfa hay was compared with uncut hay in 25 Idaho and Oregon comparisons in which fattening cattle were fed alfalfa hay, usually with a limited amount of grain or silage in addition.[117] On the average the cattle fed chopped hay gained 0.17 lb. more per head daily. From the standpoint of the amount of feed required per 100 lbs. gain, chopping the hay increased its value about 25 per cent.

For fattening cattle there is no advantage in mixing chopped or ground hay with the grain.[118] As shown in Chapter XXXI, this is sometimes done with fattening lambs heavily fed on grain, in order to lessen digestive disturbances.

1202. Pelleted or cubed feed.—This method of preparing cattle feeds is now attracting much attention. Although trials with beef cattle are limited, if increased feed intake is secured, improved performance is usually secured in terms of gain and feed efficiency. Responses are usually greatest where use is made of poor quality forages rather than high quality ones.

If pelleted cattle rations contain much less than 20 per cent roughage a reduction in feed intake and daily gain but increased feed efficiency may be secured. Fine grinding and pelleting of milo alone in a fattening ration has improved gains and feed efficiency slightly in Kansas experiments.

Pelleting or cubing of a concentrate mixture reduces wastage from wind or scattering when fed either in bunks or on the ground. Added cost may offset advantages of pelleting rations.

1203. Self-feeding.—When fattening cattle are to be fed all the grain they will eat, self-feeders are often used. As the hopper which holds the grain can be of considerable size, it requires less labor to keep it filled than to hand-feed the grain twice a day. Moreover, cattle generally gain a trifle more rapidly if self-fed than when hand-fed, even by experienced men.

There is also probably less tendency for self-fed cattle to "go off feed" than with those that are hand-fed. This is because each animal soon learns he can eat what he wishes at any time, and therefore there is not the tendency for greedy steers to gorge, as they sometimes do at feeding time when fed by hand.

These advantages are offset to some extent by the fact that more grain and less roughage are consumed per 100 lbs. gain by self-fed animals, and generally the gains are slightly more expensive than those of cattle hand-fed by a good stockman. However, the greater cost of the gains is usually offset by a higher selling price of the self-fed cattle, because of better finish.

A self-feeder should not be used when one wishes to utilize the maximum amount of roughage in fattening cattle. Also, ear corn is not well suited to self-feeding, as it tends to clog the feeder. It is therefore best to shell or grind corn for self-feeding.

In order to avoid digestive disturbances, cattle that are unused to grain are not usually self-fed grain separately until they have been brought to a full feed of grain by careful hand-feeding. Occasionally, chopped or ground hay is mixed with the grain in starting the cattle on the self-feeder. The grain in the self-feeder should be protected from rain or snow, and care is necessary to avoid clogging, as an abundance of feed should be available at all times.

When a protein supplement is used for self-fed cattle, the proper proportion of supplement is usually mixed with the

grain. If the supplement is fed free choice, the cattle are apt to eat more of it than is needed to balance the ration. However, in Oklahoma tests fattening calves did not overeat on protein supplement when self-fed, free choice, shelled corn, whole oats, and cottonseed meal, with prairie hay for roughage.[120]

Self-feeding of grain has been compared with hand-feeding in 13 experiments, in each of which one lot of cattle has been self-fed grain after they were safely on feed, while another lot was given the same grain by hand twice a day.[121] The roughages (hay or hay and silage) were hand-fed in the usual manner. Though expert cattlemen hand-fed the grain in these trials, the self-fed cattle gained 0.13 lb. more per head daily. While their feed cost per 100 lbs. gain was 26 cents higher, this was more than offset by a slightly higher selling price. On the average the net return per head over cost of feed was 87 cents per head more for the self-fed cattle, not considering the saving in labor. When cattle are fattened by less experienced men, there would usually be more advantage in self-feeding. In these trials self-feeding was just as well suited to the fattening of calves as of older cattle.

1204. Shelter; shade; hot weather.—Expensive buildings are not required for beef production. Even in a climate like that of the northern states, cattle make fully as rapid and economical gains when fattened during winter in an open shed with an adjacent exercise lot as when more warmly housed in a barn.[122] A reasonable degree of cold is a benefit rather than a detriment to liberally fed fattening cattle. This is because more heat is unavoidably produced in chewing, digesting, and assimilating their food than is needed to keep their bodies warm. (231)

In cold climates where there is considerable rain or snow during winter, it is advisable to provide a shed for shelter. Otherwise, the loss of heat in the evaporation of water from a wet skin, coupled with the loss by radiation, may be so great that food nutrients must be oxidized to keep the animal warm.

Unless the winters are unusually severe, it does not pay to provide warmer winter shelter than an open shed for beef breeding cows or for young stock, except very young calves. For cattle being fed little more than a maintenance ration, warmer shelter will save a small amount of feed in cold climates, but it is doubtful if the saving will be sufficient to justify much additional expense.[123]

In western regions where there is little rainfall, no shelter except a windbreak is commonly provided for beef cattle. Even where the winters are severe, furnishing shelter in an open shed or barn does not appreciably increase the gains of fattening cattle or save enough feed to justify the expense.[124]

In humid regions with mild winters, as in the southern states, it may likewise not pay to provide shelter for beef cattle.[125]

When cattle are fattened in a dry lot during the summer, it may be advisable to confine them to a barn or open shed, merely so that their coats do not become harsh and sunburned. Otherwise, the buyers at the central market may think that they have been fattened on grass and not offer the premium for them that cattle well fattened in the dry lot generally command.

Where the summers are very hot, it is important to provide shade for beef cattle, as has been shown in Chapter VIII.[126] (233) In the corn belt and eastward, there had best be shade for cattle on pasture, furnished either by trees or by a temporary shade. Opinions differ as to the value of shade for beef cattle in the range areas of the West, where the summers are less humid.[127]

Even when fattening cattle have shade, they usually make less rapid and economical gains in very hot weather than when it is cooler.[128]

1205. Confinement and exercise.—Beef breeding cattle and young stock being wintered should be allowed plenty of exercise in outside paddocks during the winter. Not only does the exercise itself aid in keeping them thrifty, but also the exposure to sunlight will prevent any deficiency of vitamin D. (201)

On the other hand, too much exercise for fattening cattle will make the gains less rapid and more expensive. Thus, in Kentucky trials fattening steers confined in winter to a barn and exercise lot made more rapid gains and gave a higher net return than others that had the run of a similar barn and were allowed to range at will on a 20-acre bluegrass pasture.[129]

The ordinary method of feeding fattening cattle in which they are fed as a group, having access to a common feed bunk and hay rack, is decidedly preferable to confining them in stanchions. Not only is there a saving of labor and equipment, but also the group-fed cattle will usually eat more feed, because of competition at the feed bunk, and make more rapid gains.[130] The group-fed cattle may, however, require a trifle more feed per 100 lbs. gain, because of their greater activity.

1206. The paved feed lot.—Where the soil and the climate are such that a feed lot will otherwise become a sea of mud and mire in winter, paving the lot will pay.[131] It will make the cattle more comfortable and will increase their gains, and also the pigs following the steers will be able to utilize the grain in the droppings more completely. In addition, there will be much less waste of manure.

1207. Dehorning.—Horned cattle are at a distinct disadvantage in the feedlot. They need more room than dehorned or polled cattle, they make less rapid gains, and they commonly sell at a lower price on the large markets, because of damage to hides and carcasses. It therefore pays well to dehorn feeder cattle before they are fattened for market.[132]

QUESTIONS

1. Why is it more necessary than formerly that beef cattle being fattened for market be fed well-balanced rations?
2. Compare the nutrient requirements of beef cows with those of dairy cows.
3. Compare the requirements of fattening cattle with those of cattle being carried through the winter for fattening later.
4. About how much will 100 lbs. of protein supplement, such as linseed meal or cottonseed meal, be worth for fattening cattle in comparison with grain, when added to a ration that has insufficient protein?
5. Discuss the addition of a protein supplement to grain and legume hay for fattening cattle.
6. Discuss the use of protein supplements with part non-legume roughage.
7. Under what conditions may the quality of protein in a protein supplement be of importance for fattening cattle?
8. How can urea be used satisfactorily as a substitute for part of the protein for beef cattle?
9. Discuss the value of certain combinations of protein supplements.
10. Discuss the requirements of beef cattle for: (a) Salt; (b) calcium; (c) phosphorus; (d) trace minerals.
11. What conditions are necessary for the successful self-feeding of a mixture of protein supplement and salt?
12. Discuss the requirements of beef cattle for vitamins, other than vitamin A.
13. When should a carotene or vitamin A supplement be fed beef cattle?
14. Why is good roughage important for beef cattle?
15. Discuss: (a) Adding a small amount of alfalfa to rations for fattening cattle; (b) Purdue Supplement A and other complex supplements.
16. Compare the value of supplements having only 20 to 30 per cent protein with that of a supplement having 40 per cent protein.
17. What results have been secured in experiments in which fat has been added to a ration for fattening cattle?
18. How much water do beef cattle need?
19. Should an antibiotic feed supplement be added to a ration for fattening cattle?
20. Discuss the use of stilbestrol for fattening cattle.
21. Under what conditions and for what ages of cattle is it economical to limit the amount of concentrates fed fattening cattle?
22. Define *margin* and *necessary margin.* State the effect of each of 5 factors on the necessary margin.
23. Discuss the value of beef blood for beef production, considering: (a) Rapidity and cost of gains; (b) early maturity; and (c) value of carcass.
24. How would you decide which grade of feeder steers to purchase?
25. What results have been secured in trials

in which beef-bred steers have been compared with dairy-bred steers?

26. What is known concerning the relation between the conformation of cattle and the rate and economy of gains?
27. Discuss the influence of age upon the economy of gains by beef cattle.
28. Upon what factors would you base your decision concerning the age of feeder cattle to buy?
29. Why is it important both for the beef producer and for the consumer not to carry fattening cattle to an excessive degree of fatness?
30. Discuss the results secured from the fattening of heifers.
31. Discuss the chopping of hay and other dry roughage for beef cattle; the grinding of roughage.
32. When is there an advantage in using pelleted feed for beef cattle?
33. When would you recommend the self-feeding of grain to fattening cattle?
34. Discuss the needs of beef cattle for shelter under various climatic conditions.
35. Contrast the requirements of breeding cattle and of fattening cattle for exercise.

CHAPTER XXIX

FEED AND CARE OF BEEF CATTLE—METHODS AND COSTS OF BEEF PRODUCTION—VEAL PRODUCTION

I. The Beef Breeding Herd

1208. Importance of pasture in beef production.—Pasture is the foundation of economical beef production, for it commonly furnishes much cheaper feed than do any harvested crops. Unless the beef herd is maintained on good pasture during as large a part of the year as possible, the costs will generally be high and the profits much reduced.

It has been emphasized in Chapter XIII that the productivity of pastures can be greatly increased and the forage made much more nutritious by modern methods of pasture improvement. These include the use of high-yielding pasture mixtures, proper pasture fertilization, and efficient pasture management.

During recent years outstanding advances have been made throughout this country in the general adoption of pasture improvement practices. However, even yet many farmers do not appreciate the true productive possibilities of pasture, and they give but little attention to their pasture fields in comparison with their tilled crops.

The value and use of many different grasses and legumes for pasture have been considered in detail in Chapters XIII, XVI, and XVIII. It is there pointed out that for pasture in humid regions certain combinations of legumes and grasses are generally more productive than any single grass or legume. Such high-yielding combinations are alfalfa and timothy or bromegrass, Ladino clover and grass, and lespedeza and grass. By selecting the pasture mixture that is best adapted to the local conditions, maximum yields of nutritious forage can be obtained.

The fattening of cattle on pasture is discussed later in this chapter.

1209. Establishing a beef herd.—In establishing a beef breeding herd one should start with well-bred cows of beef type, if possible, in order to secure calves that will make economical gains, mature early, and bring a high price when marketed. A purebred bull of good quality should always be used.

Recent experiments show that under most conditions beef cattle of large or intermediate size have certain economic advantages, in comparison with "compact," or "compress" cattle.[1] The calves are larger at birth and at weaning time, and in the feed lot make more rapid gains.

When fattened, the larger animals do not reach the same degree of fatness and Federal Grade so soon as the compact animals, but on a liberal fattening ration there is no significant difference in the amounts of feed required per 100 lbs. gain to reach the same degree of fatness. However, the larger cattle are more efficient when they are fattened chiefly on roughage, with a minimum amount of concentrates.

The amount of feed required by beef cows of the different sizes is approximately proportional to their liveweights. Therefore, large cows definitely need more feed than smaller ones. This is of much less importance in the case of breeding herds maintained largely on the National Forests or other public grazing land, where the grazing fees are based on the number of cows, without regard to their size.

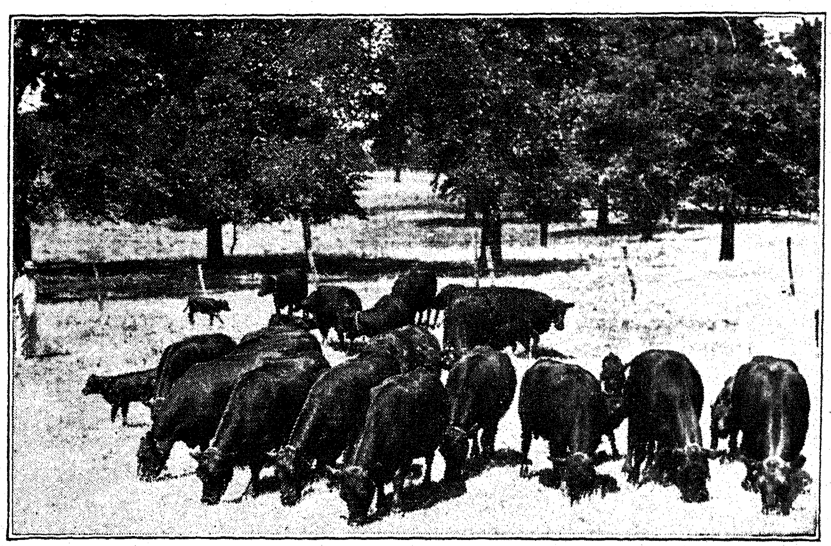
The greater amount of feed eaten by the larger cows is offset by the larger size, faster gains, and greater market weights of their calves. Also the percentage calf crop raised tends to be appreciably higher for large or intermediate cows than for those of the compact

type. In addition, with compact or comprest cows there is apt to be a greater occurrence of hereditary "dwarfism" in the calves.

There are three general systems of handling beef breeding herds. These are: (1) The regular beef method; (2) "baby-beef" production; and (3) the "dual-purpose" system. In the first two systems the calves run with their dams until weaned, none of the cows being milked. Cows producing calves intended for baby beef are, however, commonly fed a little more liberally, as is pointed out later. (1242) In the dual-purpose system beef production is combined more or less with dairying. (1216)

1210. Feeding beef breeding cows.—Where cows are kept only to raise calves for beef, the cost of their keep for an entire year must be charged against the calves at weaning time. It is therefore essential that the breeding herd be maintained as cheaply as possible, yet kept in vigorous breeding condition. Only a breeder of purebred stock who wishes to keep his herd in somewhat of "show condition" as an advertisement can afford to feed much grain to his beef cows.

Cows kept solely for beef production are commonly grazed on pasture during the growing season. The suckling calves run with their dams and no additional feed is given to cows or calves. In the fall the cows can get their living chiefly from feed that might be otherwise wasted, such as stubble or stalk fields and the aftermath of meadows. With a little foresight, the amount of such cheap feed may be increased by seeding rape



A WELL-BRED BEEF HERD

The calves from well-bred beef cows make economical gains, mature early, and bring a good price when marketed.

or clover in the small grain, and rape in the corn fields. Shade should always be supplied the herd at pasture.

The winter feed and care may range from the most intensive system, where the herd is fed in barn or shed with the freedom of exercise paddocks, to the practice followed in many range districts, where the chief feed is that furnished by the winter range on which the grass has been allowed to grow up and mature.

1211. Nutrients required by beef cows.—It has been emphasized in Chapter IX that to produce thrifty, vigorous offspring the dams must receive rations which supply sufficient protein, minerals,

and vitamins. (288–292) Fortunately, much smaller quantities of these nutrients are needed for wintering beef breeding cows than for feeding dairy cows in milk. This is because beef cows usually calve in the spring and are dry during winter. They therefore need nutrients merely to maintain their own bodies and for the growth of the fetus. As we have seen in Chapter IX, the amounts of nutrients required for the development of a calf to birth are not very large. (292)

It is for this reason that beef cows can be wintered satisfactorily on roughage alone, when some legume hay is available. If only non-legume roughage is fed, there should be added to the ration 1 lb. per head daily of a protein supplement, such as soybean oil meal, cottonseed meal, or linseed meal.

Beef cows should receive sufficient feed during the winter to keep them in thrifty condition. Otherwise, they may be unable to produce strong calves and nourish them with a good flow of milk. If they go into the winter in poor flesh, because of a shortage of feed on pasture, a little grain may be needed to get them in suitable condition before calving.

Too-liberal feeding of grain is not only extravagant but also may be actually injurious. Experienced beef producers know that the best calf crop is apt to be secured from cows kept in vigorous condition on a properly-balanced ration, rather than from cows which are fat.

Under range conditions where the beef cows must get most of their winter feed from mature and weathered grass and other forage, the supply is often so scanty in amount and poor in quality that the percentage calf crop raised is very low. (1247) Under such conditions the net income can be greatly increased by supplying enough supplementary feed to keep the cows in thrifty condition.

1212. Protein; minerals; vitamins; total digestible nutrients.—There will be no shortage of protein, calcium, or vitamins if the cows receive at least 4 to 5 lbs. per head daily of well-cured legume hay, or mixed legume-grass hay supplying this amount of legume forage. The same is true when legume or legume-grass silage forms a considerable part of the ration.

In such rations there will also be no lack of phosphorus, unless the roughage has been raised on soil deficient in this mineral. When non-legume roughage is fed with 1 lb. per head daily of protein supplement, the ration will have ample phosphorus, but there may possibly be a lack of calcium, unless the roughage was grown on soil well supplied with calcium. If no legume hay is fed, it is wise to furnish about 0.1 lb. of ground limestone or other calcium supplement per head daily.

Beef cows that have been on good pasture during summer go into winter with a considerable store of vitamin A and carotene in their bodies. (1176) Therefore, unless the winter is too long, they can be wintered successfully on a ration very low in carotene, such as straw and 1 lb. per head daily of protein supplement. However, as insurance against a lack of vitamin A, it is much safer to feed, along with such roughage as straw, at least a limited amount of well-cured hay, of silage, or of good corn or sorghum fodder. This is especially important if the cows go into winter in poor condition and depleted of vitamin A, because of drouth-stricken pastures.

Beef breeding cows that are outside in the sunlight most of the day are amply protected against any lack of vitamin D.

Plenty of salt and a proper supply of water should always be furnished the cattle. If trouble is experienced from goiter, or "big neck," in new-born calves this may be prevented by supplying the cows with iodized salt during at least the latter half of the pregnancy period. (170)

The amounts of nutrients advised for beef cows are stated in the Morrison feeding standards. (Appendix Table III.) If one is in doubt as to whether the ration he intends to feed his breeding cows is adequate, he should see how the amounts of the various nutrients in the ration correspond with the standards. If necessary, a protein or mineral supplement should be provided.

In the case of mature cows the amount of total digestible nutrients may

fall slightly below the minimum in the standard, if the cows go into winter in good flesh. On such a ration, however, the animals will probably lose in weight slightly during the winter. Cows which are not yet mature should be fed a little more liberally than full-grown ones, as they need additional nutrients for growth. Cows nursing calves in winter require more feed than those which are dry, as is shown in the feeding standards. (Appendix Table III.)

1213. Wintering cows chiefly on corn or sorghum forage.—Where corn or the sorghums thrive, these premier forage crops should generally furnish much of the roughage for the breeding herd. The crop may be fed, grain and all, as silage or dry fodder, or the grain may be removed and the stover fed either as dry stover or stover silage.

Experiments have shown that corn or sorghum silage is much more economical than the dry fodder, for it is consumed with less waste and will maintain the cows in better condition.[2] Beef cows may be wintered very satisfactorily on 50 to 60 lbs. of corn or sorghum silage per head daily and 1 lb. of cottonseed meal, linseed meal, or similar protein supplement.[3] This will keep them in good condition. Even 40 lbs. per head daily of corn silage with 1 lb. of supplement maintained cows in fair condition in an Illinois test.[4] Though the cows did not carry as much flesh as many breeders would desire, their health was not injured, and they produced vigorous calves.

In another Illinois trial beef heifers were raised on only corn silage and protein supplement, and fed this ration for 4 years until they had produced two crops of calves.[5] No ill effects of any kind were observed, and the calves were strong and vigorous.

Often it is most economical to use silage in combination with hay, straw, or other dry roughage. An excellent combination is 5 lbs. or more of legume hay and 25 to 30 lbs. or more of corn or sorghum silage.[6] Another satisfactory ration is 20 to 25 lbs. of corn or sorghum silage, with what straw the cows will eat and 1 to 1.5 lbs. of protein supplement.[7] When corn or sorghum silage is fed as the only roughage or else with non-legume roughage, it is important to feed a protein supplement.[8] A calcium supplement should also be supplied, except perhaps where the soil is high in lime.

It has been shown in Chapter XVI that corn-stover silage is satisfactory as the chief feed for wintering mature beef cows. (531) If possible, good legume [illegible] should be fed with the stover silage [illegible] 1 lb. per head daily of a high-protein supplement should be supplied, along with some hay or dry fodder.

1214. Wintering on hay and other feeds.—In the alfalfa districts of the West, alfalfa hay is widely used as the chief roughage for wintering beef cows. They can be kept in excellent condition on 18 to 25 lbs. of alfalfa hay a day, but often the cost can be reduced by combining the alfalfa with some cheaper roughage, such as prairie hay, corn or sorghum fodder or stover, or straw.[9]

In Montana trials oat hay was even better than alfalfa hay as the only feed for wintering beef cows, because of the grain it contained.[10] Sweet clover hay, native bluejoint hay, and corn fodder were also satisfactory as the only feed.

Hay made from clippings of grass pastures were too low in protein to be satisfactory as the only winter feed for beef cows in Mississippi trials, and needed supplementing with 1 lb. of protein supplement per head daily.[11]

Beef cows can be wintered very satisfactorily on hay-crop silage with a limited amount of hay. As shown in Chapter XV, the relative value of hay-crop silage, in comparison with corn silage, is much greater for beef cows than for wintering calves. (439)

In the southern states temporary winter pasture crops, such as crimson clover and rye grass or small grain, can often provide much of the feed during winter.[12] (482, 583)

The wintering of beef cows entirely or chiefly on straw has been discussed in Chapter XVII. (622)

1215. Supplementing winter range.—In those range sections where the grass or other forage is not usually covered by

snow in winter, the beef herd is wintered as largely as possible on the range. The mature, weathered winter pasture is like straw in nature, being low in protein, in phosphorus, and in total digestible nutrients. In addition, it generally has but little carotene. Severe nutritive deficiencies may therefore result if cows have no other feed for too long a time, especially if they are not in good condition at the beginning of the winter period.

Commonly, only enough supplemental feed is furnished in addition to winter range, to keep the cows from running down seriously in condition. Often a supply of hay or of silage (usually in a trench silo) is kept on hand to meet shortages of feed on the range during the winter. Others supplement the winter range by feeding cottonseed cake or some other protein supplement, when necessary.

The amount and kind of supplemental feed needed in addition to winter range is entirely a local problem, as it depends on the feed available on the range. In some areas, it does not pay to supply supplemental feed under usual conditions.[13] In other districts, supplemental feeding greatly increases the percentage calf crop, reduces the death losses, and increases the weaning weights of the calves.[14]

The poor results that follow when beef cows are wintered on a scanty supply of inferior forage are shown by the fact that beef herds wintered on pine forest ranges in the southeastern states without supplemental feed often have but a 50 per cent calf crop.[12] The average weaning weight of the calves is only about 300 lbs., and there is a 5 per cent annual death loss of the cows. Under such conditions many of the cows calve only in alternate years, as they fail to breed successfully while nursing calves. Adequate nutrition of the cows would greatly raise the calving percentage, as well as increase the weaning weights of the calves and greatly reduce the death loss.

In contrast with the poor results in such "piney-woods" herds, are those secured by Missouri commercial beef producers who kept records over a period of 14 years.[15] In these records, including more than 10,000 calves, the calf crop averaged 95.5 per cent, the calves gained 1.76 lbs. a day, and the average weaning weight was 445 lbs. at 207 days of age.

The need for supplementing winter range will depend to a considerable extent on the quantity and quality of the range forage the cows have secured the previous summer. If the season has been favorable, the cows will go into winter in good flesh and with a good store of vitamin A in their bodies. They can then draw on their body reserves to some extent during winter without injury. On the other hand, in case of severe summer drouth, their bodies will be depleted, and bad results will follow unless their winter feed is adequate.

Montana trials show that when the summer feed has been good on the range and the calves are weaned by mid-October, cows may lose 50 to 125 lbs. in weight during winter and still produce normal calves.[16] In these tests cows fed 1 to 2 lbs. of cottonseed cake per head daily in winter, in addition to range pasture, maintained their weights better than did cows fed no supplement. However, the weaning weights of the calves the next season were not enough greater to cover the cost of feeding the cottonseed cake to all of the cows. A practical way to reduce the cost is to separate out the thinner and weaker cows and feed the supplement only to them.

In Oklahoma trials good results were secured when cows were fed 8 lbs. of alfalfa hay or else 2.6 lbs. of cottonseed cake per head daily to supplement winter range.[17] The cost was less, on the average, than when they were wintered on prairie hay plus 1.3 lbs. cottonseed cake.

In South Dakota experiments 8 to 10 lbs. of early-cut native hay per head daily was a better supplement to winter range than 1 lb. of 40-per-cent-protein cubes, but the same amount of late-cut native hay was much less satisfactory.[18]

1216. Feeding dual-purpose cows. —Where dual-purpose cows are kept and milked so as to secure dairy products as well as a crop of calves, the cows should

be fed the same as dairy cows and the calves should be raised much like dairy calves, except that they should be forced to rapid growth through more liberal feeding. Since most dual-purpose cows yield only a moderate amount of milk, it is especially important that they be fed strictly according to their actual production, instead of being given more concentrates than they will pay for at the milk pail.

Sometimes the "double nursing" method is followed, in which about half the cows in the herd nurse two calves each and the others, from which the calves have been taken, are milked. It is essential that all the cows nursing calves be good milkers, as otherwise the calves will not make the gains desired.

1217. The beef bull.—Under farm conditions the bull should be kept separate from the herd of cows except at the breeding season. This plan is also often followed in range herds, so that the calves will come within a certain time and so that the bulls will have an opportunity to get in good condition before the next breeding season.

A vigorous bull 3 years old or over should serve 40 to 50 cows when hand-mated, and 25 to 30 when he runs with the cows on pasture during the breeding season. On the western range the average number of cows per bull is about 25, except in rough and mountainous country, where a bull to every 15 to 20 cows is a common proportion. A yearling bull should be hand-mated to no more than 10 to 12 cows during the breeding season, and a 2-year-old to no more than 25 to 30 cows. It is not wise to allow young bulls to run with the cows on pasture during the breeding season.

The same general principles apply to the feeding and care of beef bulls as for dairy bulls. (**1155–1157**) The bull should be kept in good, thrifty condition but not fat. Previous to the breeding season he should be well fed, and concentrates should be added at other times, as needed, to keep him in proper condition. Some prefer to feed only a limited amount of silage to a bull prior to the breeding season or during it, as he may otherwise become too paunchy. (**1156**) If a bull is a "hard keeper" and requires an abnormal amount of feed to keep him in proper flesh, he should be discarded, for he cannot be expected to sire cattle which will make economical gains. The importance of using a good purebred sire has been emphasized in the previous chapter. (**1189**)

II. Raising Beef Cattle

1218. The beef calf.—Most beef producers prefer to have the calves born in the spring, because the cows can then be wintered more cheaply than when they calve in the fall. If the cows are well fed during the winter and have proper shelter, it is generally best to have them calve in the early spring or even in late winter.

Early calves, coming before the spring work starts, can be given more attention. When the cows go to pasture in the spring, the calves will be old enough to use the increased milk flow to advantage. Also, early calves can utilize summer pasturage better than late calves and will be much larger and in better condition in the fall.

Especially in the southern states, fall calves may be more profitable than spring calves, if plenty of good feed is provided during fall and winter for the cows and calves.[19] The calves will usually bring a good price as fat slaughter calves at weaning in early summer, or they can be finished for marketing at about a year of age, when the supply of well-fattened young cattle is limited.

When the calves are born on pasture, the cows usually have no difficulty in calving and need little attention. Even when they calve in winter, beef cows, except 2-year-old heifers, are not apt to need assistance at calving time, as is sometimes the case with dairy cows. This is because their calves are rather small at birth, generally weighing only 60 to 75 lbs.

Under the simplest method of beef production, the calves are not fed any grain or other concentrates while they are with their dams on pasture during the summer. Suckling calves should gain

1.25 to 1.75 lbs. or more a day, if their dams give a good flow of milk.

Arkansas studies show that the rate of gain of suckling calves depends to a considerable extent on the milk production of their dams.[20] The milk yield of 77 beef cows was determined by milking out half of the udder on one day each month and the other half the following day. The average total yield per cow was 1,498 lbs., with a range from a high of 2,458 lbs. to a low of only 312 lbs. The calves from cows that averaged more than 13 lbs. of milk a day at peak production, weighed 475 lbs. at weaning, while those from cows that produced less than 6.5 lbs. at maximum daily yield averaged only 354 lbs. These data show the importance of good milk production by the cows.

All bull calves that are not to be retained for breeding should be castrated, preferably before fly time and when from 1 to 2 months of age. Calves to be fed for the market should be dehorned, unless it is the intention to sell them as fat calves at weaning time. A good plan, where practicable, is to prevent the growth of the horns by using a caustic pencil before the calves are 3 weeks old.

Spring calves are commonly weaned in the fall by separating them from their dams. To avoid a loss of weight at this time, it is best to teach farm-raised calves to eat grain and hay before they are weaned, and then feed them well when they are taken from their mothers.

In dual-purpose herds the same methods may be used for raising the calves as in dairy herds. Though beef-type calves raised chiefly on skimmilk will not make as rapid gains to 6 months of age or be as fat as calves that nurse their dams, they will make fully as rapid and economical gains when later fattened for market.[21]

1219. Creep-feeding suckling calves.—Beef calves that are running with their mothers on good pasture need no grain, in addition to the pasture and their dams' milk, to make satisfactory growth. However, supplying grain for the calves by means of a creep is often profitable with farm-raised calves under certain conditions.

Creep-feeding is advisable in the case of purebred calves on which maximum growth is desired. Experiments have shown that it also is generally profitable, unless the pasture is much better than average, for well-bred calves that are to be sold for beef at weaning time or shortly thereafter. Fall or early winter calves should be creep-fed during the barn-feeding period.

On the other hand, creep-feeding does not pay, except when pasture is scanty, for calves to be fattened on grain for 4 or 5 months or longer, after weaning.[22] When spring calves are to be sold as feeders in the fall, it will pay to creep-feed them on good pasture only if they will probably bring a higher price per hundredweight, because they are heavier and fatter. Often men who buy calves for fattening prefer calves in only moderate condition, because such calves, if thrifty, will make the cheapest gains.

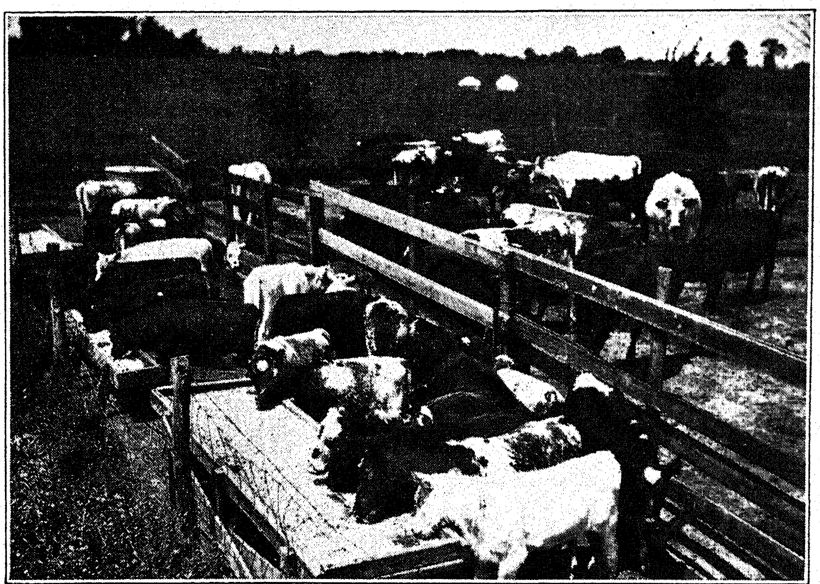
In 31 tests of creep-feeding, the calves which were creep-fed while nursing their dams gained 1.83 lbs. daily, which was 0.38 lb. more than for others not creep-fed.[23] The difference in total gain per calf for these trials, which averaged 153 days in length, was 58 lbs. The total amount of grain and other concentrates eaten per calf was 524 lbs., including that consumed by the cows while the calves were learning to eat. For each 100 lbs. of additional gain, the creep-fed calves were therefore to be charged with 903 lbs. of concentrates. In 23 tests in which the selling prices were reported, the creep-fed calves were worth $1.21 more per hundredweight at weaning time. In most of these tests the greater gains and the increased selling price paid well for the concentrates fed.

If the pasture furnishes an abundance of feed and if the cows are good milkers, creep-fed calves may not eat enough concentrates in the creep to cause much difference in rate of gain. Thus, in 4 North Carolina tests calves creep-fed on native reed and cane pasture ate an average of only 130 lbs. of concentrate mixture in 168 days and gained only 12

lbs. more per head than others not creep-fed.[24] Creep-feeding was therefore not worth while.

Because milk is rich in protein and good pasture is also fairly high in protein, merely corn or other grain, without any protein supplement, is satisfactory for creep-feeding on such pasture. Mixtures of grain and a small proportion of protein supplement are often preferred, however, as they may be slightly more palatable. In 3 Missouri tests calves creep-fed a mixture of 9 parts of shelled corn and 1 of cottonseed meal gained slightly more than others fed only shelled corn or a mixture of 2 parts corn and 1 part oats.[25] They also sold for 50 cents more per hundredweight and gave a slightly larger net return. In Oklahoma trials calves ate considerably more of a creep mixture containing molasses than others ate of a mixture without molasses.[26] There is no advantage in grinding corn or oats for suckling calves.

The creep should be built at a spot in the pasture where the calves tend to gather, as at the watering place. It is an enclosure with openings of such size that the calves can enter while the cows are kept out. At first, the cows should be allowed to enter the enclosure with the calves and eat grain, so that the calves will learn to take it. The grain can be conveniently fed in the creep by means of a covered self-feeder which will hold a supply for several days.



Beef Calves Eating Corn in a Creep on Pasture

Feeding grain by means of a creep to well-bred calves running with their dams on pasture generally pays if the calves are to be sold as fat calves at weaning time or shortly thereafter. The entrance to the creep cannot be seen in this photograph.

In Missouri tests the creep-feeding of calves that were running with their dams on pasture proved preferable to keeping the calves in a separate enclosure where they were fed grain, and turning them with the cows to nurse only twice a day.[27]

1220. Wintering calves.—Calves being wintered for later fattening must be fed primarily on roughage, in order to keep the cost of feed as low as possible. While the ration must be cheap, it is essential that the calves be kept growing thriftily. Sufficient protein, minerals, and vitamins must be provided to meet the requirements of animals of this young

age, or they will fail to make the desired growth.

The amounts of nutrients required per head daily for wintering calves and yearlings of various weights are shown in the feeding standards in Appendix Table III. Also, several example rations suited to various conditions are given in Appendix Table VII.

Many experiments have been conducted to compare various rations and to find the best methods of wintering calves which are later to be handled in different ways.[28] These experiments have shown that if the calves are to be pastured during the following summer without grain being fed in addition, the gain during the winter should not be too large, or the summer gains on pasture will be greatly reduced.

If the summer grazing will probably be good, it is generally advisable to feed calves so they will gain at least 0.75 to 1.00 lb. per head daily. This will keep them thrifty, produce good growth, and prevent them from losing much in condition. The gains will be sufficient to pay for the feed consumed during the winter, and hence the cost of the calves per 100 lbs. in the spring should be no greater than it was in the previous fall when they came off pasture.

If the cattle are to be fed grain on pasture the following season, or if they are to be fattened in dry lot in spring and summer, it is usually best to feed sufficient grain or other concentrates in winter to keep them improving in condition, or degree of fatness.

Feeding 2 lbs. or more of grain per head daily in winter may also be most profitable when the cattle are to be grazed on good pasture, without grain until midsummer, and then finished for market by full feeding grain on pasture or in dry lot. The fattening of calves throughout the winter in baby beef production is discussed later. (1242)

If the cattle will have only rather poor pasture in summer, it may be best to limit the winter feed so that they will gain only about 0.50 lb. per head daily. It is almost always advisable to secure at least this much gain during the winter, instead of feeding the calves so scantily that they grow in skeleton, but merely maintain their weights. If they do not gain during the winter, all the feed and labor is spent just for carrying them over to spring. The cost of the calves per 100 lbs. live weight in the spring will then be considerably greater than if they had been fed so as to make reasonable gains.

Many men who fatten western feeder cattle during the spring and summer, buy calves in the fall and carry them through the winter, instead of making their purchases in the spring. They find that they can generally get calves of good quality more readily in the fall, when the supply on the market is greatest. By carrying the calves through the winter, they dispose of much farm-grown roughage. Also, if the calves are fed economical rations, the cost per 100 lbs. will usually be less in the spring than the price at that time for animals of similar quality on the feeder markets.

1221. Rations for wintering calves.—In the alfalfa districts of the West, alfalfa hay is a standard ration for wintering calves or older cattle. If calves are fed all the good alfalfa hay they will clean up reasonably well, they will eat 12 to 20 lbs. of hay a day, depending on their size, and should gain about 0.75 to 1.0 lb. per head daily. When thus fed, they may waste about 2.0 to 2.5 lbs. of hay a day, but this refuse hay can often be fed to older stock being carried through the winter.

Well-cured clover hay or mixed clover-and-grass hay is about equal to alfalfa hay in value for calves. Unless hay from the grasses is cut earlier than usual, it is too low in protein to be satisfactory as the only feed. Good results are secured when good-quality timothy hay, prairie hay, or other grass hay is fed with 0.5 to 1.0 lb. per head daily of cottonseed meal or other protein supplement.

By liberal nitrogen fertilization, combined with early cutting, native hay containing a high percentage of protein was produced on a mountain meadow in recent Colorado trials.[29] Such hay would furnish plenty of protein, even for calves.

To reduce the cost, it is often ad-

visable to feed, along with alfalfa hay or other legume hay, some cheap roughage, such as corn or sorghum fodder or stover, or even straw. Calves fed 4 to 6 lbs. of alfalfa hay per day, with what straw they will eat, do not make much gain in weight, but can be carried through the winter in thrifty condition. By adding to such a ration 2 or 3 lbs. of grain per head daily, satisfactory gains can be secured.

In many sections of the country, silage from corn or the sorghums provides the cheapest roughage for calves. An excellent ration is 3 to 4 lbs. alfalfa hay and sufficient corn or sorghum silage to produce the desired gain in weight. On this amount of legume hay and 25 lbs. of corn silage, calves should gain a pound or more a day. A somewhat larger amount of sorghum silage will be needed to produce this gain. Unless at least 3 lbs. of legume hay are fed per day with corn or sorghum silage, a protein supplement should be added.

Contrary to some earlier opinions, cattle fed silage during the winter will make just as good gains on grass the following summer as others that have made similar winter gains on dry feed.

Very satisfactory gains are made when calves are wintered on a sufficient amount of corn or sorghum silage, plus 0.75 to 1.0 lb. per head daily of a protein supplement, such as cottonseed meal, soybean oil meal, or linseed meal. When thus used to balance the ration, 100 lbs. of such a supplement are worth as much as 300 lbs. of alfalfa hay.

Because of the lack of grain in hay-crop silage, on this silage it is necessary to feed calves 2 to 3 lbs. or more of grain per head daily to make as much gain as they will on corn silage with 1 lb. of protein supplement. (439)

Because wheat bran has only a medium protein content, Kansas experiments have shown that it takes 2 lbs. of bran to produce as good results as 1 lb. of cottonseed meal or cake per head daily, when used as the protein supplement in a wintering ration.[30] Other experiments by the Nebraska and Kansas Stations have shown that when protein supplements are high in price compared with farm grain, 2.0 lbs. of ground barley, oats, wheat, or grain sorghum can be used in place of 0.75 to 1.00 lb. of protein supplement, such as cottonseed cake or meal.[31] Corn is too low in protein to be used alone, but an allowance of 1.0 lb. corn and 0.75 lb. cottonseed cake, fed with silage or other suitable non-legume roughage, gives good results.

Corn-stover silage or silage made from grain-sorghum stover should not be used as the only roughage for calves, if more nutritious roughage is available. When such silage or dry corn or sorghum stover is the chief roughage, it will be necessary to feed some grain to keep the calves in good condition.

Sometimes straw is used as the only roughage for wintering calves, but this is not advisable under usual conditions, for straw is very low in total digestible nutrients and deficient in protein and carotene. When straw is thus fed, the calves should receive 1.0 lb. of protein supplement per head daily, and 0.1 lb. of ground limestone or other calcium supplement should also be supplied. At least 4 or 5 lbs. of well-cured hay had best be fed with straw, instead of using straw as the only roughage, or else it should be fed in combination with a limited amount of silage. In 3 Kansas trials wheat straw was unsatisfactory as the only roughage for calves, even when diluted molasses was sprinkled over it and protein and mineral supplements were fed.[32]

In the Southwest and in the South the calves often get most of their winter feed from winter range or pasture. In addition, a sufficient amount of protein supplement should be fed to pro[illegible] the desired gain in weight.[33] Wi[illegible] calves chiefly on pasture wher[illegible] weather permits, is usually much ch[illegible] than wintering them on harvested [illegible]

1222. Wintering yearlings [illegible] older cattle.—Yearlings and older [illegible] that are being carried through the [illegible]nter for later fattening can make even greater use of cheap roughages than can calves. Therefore, unless grain is very low in price, they should generally be wintered

on roughage alone, when they are to be grazed on pasture without grain the following summer. Of course, a small amount of a protein supplement should be added if it is needed to balance the ration. When the cattle are to be finished for a summer or early fall market by feeding them grain or other concentrates in addition to pasture, then some grain is commonly fed during the winter, especially towards spring.

Extensive experiments have been conducted at various stations and by the United States Department of Agriculture to compare various rations for wintering yearlings and older stocker cattle.[34] (Cattle being wintered for later fattening are called stockers.) The recommendations given in the Morrison feeding standards for such cattle are based upon the results of these investigations. (Appendix Table III.) Likewise, the example rations given in Appendix Table VII have been computed from the results of these studies.

While stocker cattle must be wintered cheaply, they should be fed so as to make some gain in weight. The most desirable amount of gain will depend on how they are to be handled the following summer.

Yearlings and older cattle will make good gains when wintered on a full feed of legume hay or of mixed legume-and-grass hay. Even grass hay of good quality, which has been cut reasonably early and is therefore fair in protein content, is satisfactory as the only feed for such stocker cattle. If the hay is late-cut or of poor quality, it is best to feed about 1 lb. per head daily of protein supplement. To reduce the expense somewhat, the allowance of alfalfa hay or other good hay [illegible] kept somewhat below the amount [illegible] cattle will clean up.

Except in certain alfalfa districts of [illegible] West, feeding hay alone often makes [illegible] ration unduly expensive. To reduce [illegible] cost, such cheap dry roughage as [illegible] or else corn or sorghum stover can be satisfactorily fed with at least 3 or 4 lbs. of legume hay per head daily. When most of the roughage is of low grade, it will be necessary to add 2 to 3 lbs. per head daily of grain or other concentrates to secure fair gains during the winter.

Corn or sorghum silage or silage from other suitable crops is excellent as part of the roughage, or even as the only roughage, for wintering stocker cattle. Since corn or sorghum silage is low in protein, at least 3 or 4 lbs. of legume hay per head daily should be fed with it, or else 1 lb. of protein supplement. It has been shown in Chapter XVII that a crop of corn or sorghum has a much greater feeding value for beef cattle when it is ensiled, than when it is fed as dry fodder. **(534, 554)**

In range regions where there is not too much snow in winter, winter range is commonly used as much as possible for stocker cattle. Provision should always be made for supplemental feed when the supply of feed on the range is insufficient. For this purpose hay may be stacked against time of need, or silage can be stored in a trench silo.

To supplement the mature, weathered forage, the cattle need 1 lb. or more per head daily of a high-protein supplement, such as one of the oil meals or cakes. In addition, minerals, besides salt, should be provided when needed, as advised in the preceding chapter. **(1168–1174)**

In farming districts, stalk and stubble fields can often furnish much of the feed for stocker cattle during the fall and early winter. In certain sections they are often wintered chiefly on rough land on which no cattle have been grazed in summer.

1223. Raising beef heifers and bulls.—In raising beef heifers and bulls for the breeding herd, the rations should be somewhat more liberal during the first and second winters than in the case of stocker cattle which are later to be fattened for market. It is very important that they be fed so that they will develop into vigorous animals of the proper size for their breed.

Unless at least 3 to 5 lbs. of good legume hay are fed per head daily, or an equivalent amount of legume silage, sufficient protein supplement should be added to balance the ration. Care should also be taken that there is no deficiency

of carotene or of minerals. In particular, it is wise to include in the ration some well-cured hay (legume, if possible) or some silage, in order to supply plenty of carotene. If no legume roughage is fed, a calcium supplement should be furnished, and if there is any danger of a lack of phosphorus, then bone meal or some other safe phosphorus supplement should be provided.

Corn or sorghum silage is excellent roughage for beef heifers, when fed with 1 lb. per head daily of high-protein supplement. In Kansas tests yearling beef heifers became too fat when fed all the silage they would eat, with 1 lb. of cottonseed cake per head daily.[35] Feeding 35 to 40 lbs. a day of silage with what wheat straw they cared for, plus the protein supplement, kept them in the desired condition.

In purebred herds, young cattle are commonly fed with more liberality than in commercial beef herds. The rations which have been suggested for wintering dairy heifers and young dairy bulls are well suited for use with such cattle, except that more concentrates (chiefly farm grain) will be needed in the case of animals which are being fitted for sale or show.

In commercial beef herds the heifers must be raised as economically as possible, and therefore they must be wintered almost entirely on roughage. With good legume hay and silage from corn or sorghum for roughage, little or no grain is necessary. If lower grade roughages are used, enough concentrates should be added to keep the cattle in thrifty, growing condition at all times.

Even when none of the roughage is legume, 1 lb. per head daily of such a protein supplement as cottonseed meal, soybean oil meal, or linseed meal will supply enough protein, either for calves or yearlings. Any additional amount of concentrates that is needed may consist of corn, barley, oats, or other grain. When half the roughage is legume hay, the remainder may consist of straw, corn or sorghum stover, or other rather low-grade roughage.

1224. Age to breed.—Under farm conditions beef heifers are commonly bred to calve when 24 to 36 months old. When heifers calve as 2-year-olds, they must have made excellent growth prior to calving and must have plenty of feed during the next year, or they are apt to be permanently stunted in size.

Under range conditions, unless the heifers are well developed by the time they are bred and receive sufficient feed during pregnancy, they should not calve until 3 years of age. Small 2-year-old heifers are apt to have trouble in calving, and even with careful assistance, the death loss of the heifers is appreciable and of the calves still greater.

If ranch heifers are to be bred to calve when 2 years old, they should weigh 650 to 700 lbs. when bred, and they should be fed during their second winter so that they will make satisfactory growth and be in thrifty condition at calving time.[36]

It is often advised that in order to lessen difficulty in calving, yearlings should be bred to a small-type, fine-boned bull. However, this may not make much difference in the size of the calves.[37]

In recent Oklahoma experiments heifers and cows were wintered on native range pasture plus 1 lb. of cottonseed meal pellets per head daily.[38] Heifers bred to calve first as 2-year-olds did not develop into as large cows as did those calving a year later, but produced just as many calves later, and their calves were as heavy at weaning. The cow cost per calf weaned was less for cows calving first at 2 years.

Similar results were secured in Utah and Oregon experiments.[39] In the Utah trial the cattle grazed on typical mountain range in summer and were wintered in a valley on hay and pasture. At 6 years of age, the cows calving first when 2 years old had weaned an average of 1,236 lbs. of calves per cow, in comparison with only 865 lbs. for those not calving until 3 years of age.

Differing from these results, in Kansas trials when heifers were wintered on

roughage alone and calved at 2 years of age, they failed to reach normal size.[40] Also, the average weight of their calves at weaning time was only 348 lbs. Compared with this, the average weaning weight of the calves from heifers raised similarly, but calving as 3-year-olds, was 405 lbs. Feeding the heifers a liberal allowance of grain in winter largely prevented the ill-effects of early breeding in the Kansas trials, but this method was expensive under range conditions. It was concluded that the most practical method under range and semi-range conditions was to raise heifers without grain and breed them to drop their first calves at 3 years of age.

1225. Normal growth of beef cattle.—Very few data have been published showing the weights of beef cattle of the various breeds at different ages. The following table gives the weights of females and of steers of the 3 important beef breeds in the purebred herds of the California College of Agriculture.[41] While these figures are averages for only a relatively few animals and in one herd, they are of interest in showing the rates of growth of beef cattle.

Weights of purebred beef cattle at various ages

	1 Mo. Lbs.	6 Mos. Lbs.	12 Mos. Lbs.	18 Mos. Lbs.	24 Mos. Lbs.	30 Mos. Lbs.	Mature Lbs.
Females							
Aberdeen-Angus	127	414	669	861	1,018	....	1,292
Hereford	129	401	676	855	1,031	1,097	1,453
Shorthorn	124	440	703	869	1,033	1,166	1,468
Steers							
Aberdeen-Angus	122	433	...	...	....	....	....
Hereford	132	476	850	...	....	....	....
Shorthorn	131	474	819	...	....	....	....

It will be noted that at 1 month of age there was no significant difference in weights of the heifers and the steers, but at 6 months and 12 months the steers were heavier.

In a more recent California study, the average weights of Hereford females were 300 lbs. at 122 days, 499 lbs. at 244 days, 657 lbs. at 364 days, 824 lbs. at 483 days, 912 lbs. at 608 days, 1,006 lbs. at 732 days, 1,142 lbs. at 3 years, 1,216 lbs. at 4 years, and 1,274 lbs. at 6 years.[42] In this later study Hereford bulls averaged 336 lbs. at 124 days, 605 lbs. at 248 days, 872 lbs. at 369 days, 1,077 lbs. at 487 days, 1,237 lbs. at 602 days, and 1,365 lbs. at 752 days.

III. Rations for Fattening Cattle; Fattening on Pasture

1226. Rations for fattening cattle.—The nutrient requirements of fattening cattle have been considered in detail in the preceding chapter. Information is there given on such questions as the need or advisability of feeding a protein supplement with various types of rations, the necessity of feeding a calcium or phosphorus supplement with certain rations, and the amount of grain that should be fed to various classes of cattle and under different conditions.

Example rations, adapted to various regions, are given in Appendix Table VII for the fattening of calves, yearlings, and 2-year-olds. These rations are balanced according to modern feeding standards. (Appendix Table III.)

1227. The cereal grains.—In most grain-growing regions, the cereal grains are the chief concentrates fed to beef cattle, and they are unexcelled for this purpose, when fed so as to correct their deficiencies and to take advantage of their great merits. (**680**)

All of the grains can be used satisfactorily for beef production. The choice between them will depend on the price and availability. In all sections where corn is a leading grain crop, it is commonly fed as the only grain or at least as the chief grain to fattening cattle. In the sorghum belt the grain sorghums take

the place of corn, and in the northwestern states the small grains—barley, oats, wheat, and rye—are widely used. Detailed information is given in Part II concerning the relative values of the different grains and other carbohydrate-rich feeds for beef cattle.

1228. Correcting the deficiencies of the grains.—Good legume hay largely or entirely corrects the lack of protein in the cereal grains and also supplies an abundance of calcium and of carotene. Rations consisting merely of legume hay and grain are therefore satisfactory for all classes of beef cattle. Whether or not it will pay to add a protein supplement to such a ration for fattening cattle will depend on the age of the cattle, on the kind of legume hay, and on the kind of grain, as has been pointed out in the preceding chapter. The example rations in Appendix Table VII show definitely whether a protein supplement is needed with various rations for cattle of different ages, and also the amount of supplement to be fed, if one is needed.

Rations made up of only grain and non-legume roughage are much too low in protein to be satisfactory for beef cattle. Also, such rations are apt to lack calcium, and they may be deficient in phosphorus and in carotene. Cattle fed such an unbalanced ration not only make slow and expensive gains, but also they are apt to go off feed and to suffer from digestive disturbances. Because of their poor gains, they do not become so fat as those fed balanced rations and consequently they sell for a considerably lower price.

The poor results on an unbalanced ration are shown by 8 experiments in each of which one lot of steers, 2 years old or older, was fed a ration consisting of only corn and protein-poor roughage (timothy hay, prairie hay, corn stover, or kafir stover), while another lot was fed corn and good legume hay.[43] The steers fed corn and legume hay gained 2.3 lbs. daily, on the average, and required only 689 lbs. corn and 575 lbs. hay for each 100 lbs. gain. On the other hand, those fed the unbalanced ration gained only 1.7 lbs. a day and ate 930 lbs. corn and 832 lbs. hay per 100 lbs. gain, thus requiring 36 per cent more corn and 44 per cent more hay for each 100 lbs. of gain.

It should be borne in mind that these great differences occurred with cattle that were 2 years old or older. With calves or yearlings the results from feeding unbalanced rations are even worse.

1229. Protein and other supplements.—The protein supplements most commonly used for beef cattle in this country are soybean oil meal, cottonseed meal, and linseed meal. However, several other supplements are often used, including soybeans, peanut oil meal, distillers dried grains, and corn gluten meal. Occasionally, meat scrap, tankage, or fish meal is included in supplemental mixtures for beef cattle. Wheat bran, wheat mixed feed, and wheat middlings are too low in protein to be satisfactory as the protein supplement for fattening cattle, but may be used in rations for carrying cattle through the winter.

The use and relative values for beef cattle of all these and still other protein supplements are discussed in the chapters of Part II. The quality of protein in beef cattle rations has been considered in the previous chapter. Information has also been given there concerning mixtures of protein supplements that are especially satisfactory for fattening cattle. (**1167, 1178**)

Adding an antibiotic feed supplement to a ration for fattening cattle, and the use of diethylstilbestrol have also been discussed in the preceding chapter. (**1181, 1182**).

1230. Legume hay; alfalfa meal; mixed hay.—Because of its richness in protein, calcium, and vitamins, legume hay of good quality is the best of all roughages for beef cattle. It is especially useful in keeping breeding stock in thrifty condition. Even in the case of fattening cattle, much better results are usually secured when the ration includes some legume hay than when the only roughage is grass hay or other non-legume dry forage. This is true although

sufficient protein supplement is fed to make good the lack of protein in the non-legume ration.

The results with legume hay can generally be equaled only when excellent silage, such as that from corn or sorghum, is fed as the chief roughage, and there is supplied in addition not only a sufficient amount of a good protein supplement, but also about 0.1 lb. per head daily of ground limestone or some other calcium supplement.

When the only roughage for fattening cattle is of poor quality, the gains are generally increased by adding a little alfalfa hay or alfalfa meal to the ration. As has been pointed out in Chapter II and in the preceding chapter, this not only helps supply protein, but also furnishes other factors which are needed for efficient digestion in the rumen, including trace minerals and certain unidentified factors. (45, 1178)

The effect of adding alfalfa to such a ration is well shown by 3 recent Ohio experiments.[44] Cattle full-fed corn-and-cob meal, with late-cut, poor timothy hay, enough soybean oil meal to balance the ration (1.5 lbs.), and a mineral mixture, gained an average of 1.72 lbs. per head daily. Others fed 3.5 lbs. of dehydrated alfalfa in place of the soybean oil meal gained an average of 2.07 lbs., and reached a better finish. In these trials 100 lbs. of dehydrated alfalfa was equal to 51 lbs. soybean oil meal plus 21 lbs. corn-and-cob meal and 11 lbs. hay. Because the cost of the dehydrated alfalfa per ton was as high as that of soybean oil meal, the feed cost per 100 lbs. gain was higher on the ration with the alfalfa.

In all probability the addition of a little high-quality alfalfa or other legume hay to such a ration would have had a similar effect in improving the gains and the finish of the cattle.

Good-quality mixed hay containing considerable legumes is a satisfactory roughage for beef cattle. The value per ton in comparison with legume hay will depend on the proportion of legumes and the quality of the hay.

1231. Grass hay; other non-legume dry roughages.—It has been shown in Chapter XVIII that ordinary grass hay is worth considerably less than legume hay for beef cattle. (**565**) If plenty of protein supplement and also a calcium supplement are supplied, fattening cattle full-fed on grain make satisfactory gains with high-quality grass hay for roughage. However, the value of the grass hay will be decidedly lower than that of legume hay, because so much protein supplement is needed to balance the ration.

In 3 recent Kansas trials western wheatgrass hay and intermediate wheatgrass hay were compared with sorghum silage as the only roughage for fattening yearling steers.[45] On the average the cattle gained 0.6 lb. less per head daily on the wheatgrass hay and sold for 61 cents less per hundredweight.

Fattening cattle and other beef cattle are often fed dry corn or sorghum fodder, or else shock corn. It has been emphasized in Chapter XVII that a much greater feeding value is secured per acre when a corn or sorghum crop is fed as silage than as dry fodder. (**534, 548**) As in the case of grass hay, better results are secured when fattening cattle are fed some legume hay or some silage, along with corn or sorghum fodder, than when the fodder is the only roughage.

Corn or sorghum stover is satisfactory as part of the roughage for wintering beef breeding cows or young cattle. However, stover is too low in nutrients to be very useful for fattening cattle. (**537, 551**)

Straw from the small grains is even lower than corn or sorghum stover in nutrients. It is therefore unsuited to form any considerable part of the roughage for fattening cattle. (**622**) However, if there is a shortage of better roughage, straw can replace part of the silage or hay usually fed.

Experiments reviewed in Chapter XXII show that cottonseed hulls, which are widely used for beef cattle in the South, are worth slightly more per ton than corn stover or sorghum stover, but somewhat less than good grass hay.

(826) Since cottonseed hulls do not supply carotene, they give the best results when fed along with silage or well-cured hay.

1232. Silage.—Wherever corn or the sorghums thrive, silage from these crops has proved of great value in cheapening the cost of beef production. It has been emphasized in Chapter XVII that a much greater feeding value per acre is secured when corn or sorghum is ensiled than when the crop is fed as dry fodder. (534, 548)

Experiments have shown that on well-balanced rations in which well-eared corn silage is the chief roughage, fattening cattle will make rapid gains and reach a satisfactory finish on only a moderate allowance of concentrates. (1185) Hay-crop silage may produce as good results as corn silage when fattening cattle are full-fed on grain. (439) On the other hand, when a maximum amount of roughage and a minimum of grain is fed, it will take more grain to produce satisfactory gains and finish with hay-crop silage. This is because it lacks the considerable amount of grain that there is in well-eared corn silage.

Trials at various stations have shown that it is commonly more economical to give fattening cattle twice a day all the silage they will clean up without undue waste than to limit the amount of silage.[46] Two-year-old steers full-fed on corn, legume hay, and silage will eat 30 to 40 lbs. of silage a day during the first month of fattening and gradually less as feeding progresses, until during the last month they will eat only 10 to 20 lbs. per day.

Calves and yearlings will eat considerably less silage per head daily than do 2-year-olds. Calves fattened on a liberal amount of grain will usually eat 8 to 16 lbs. of silage a day, in addition to hay, early in the fattening period and not over 6 to 8 lbs. a day towards the end.

Kentucky experiments show that if the supply of silage is used up before the fattening cattle are ready for market, they can be changed gradually to good hay as the only roughage without difficulty.[47]

Since corn silage and sorghum silage are low in protein, it is important, when such silage is fed, to balance the ration with a sufficient amount of protein supplement. (1162)

Corn or sorghum silage can be used satisfactorily as the only roughage for fattening cattle, if enough protein supplement is fed to balance the ration and if 0.1 lb. per head daily of ground limestone or other calcium supplement is also supplied. Under usual conditions, however, it is wise to feed fattening cattle at least a small amount of well-cured hay or other dry roughage in addition to silage. Cattle fed silage as the only roughage often seem to show a desire for some dry forage, and may consume more feed and make more rapid gains when it is supplied.[48]

For example, in a recent Oklahoma trial adding only 1 lb. per head daily of alfalfa hay to a ration of ground kafir grain, sorghum silage, protein supplement, and minerals for fattening calves increased the daily gain 0.23 lb. and brought a better net return.[49] Adding dehydrated alfalfa pellets had no better effect than supplying alfalfa hay.

In earlier Kansas experiments calves fed sorghum silage as the only roughage, with corn, protein supplement, and 0.1 lb. ground limestone per head daily, gained as rapidly or nearly as rapidly as did others which received alfalfa hay in addition to silage for roughage.[50]

The value of hay-crop silage, in comparison with corn silage for fattening cattle and other beef cattle, has been discussed in Chapter XV. (439) The use of silage for wintering beef breeding cows and young stock has been discussed earlier in this chapter.

1233. Fattening cattle on pasture.—It has been emphasized previously that good pastures are essential for economy in maintaining a beef breeding herd and in raising young cattle. Whether it will be more profitable to fatten cattle on pasture or to fatten them in dry lot on harvested feeds will depend on several factors.

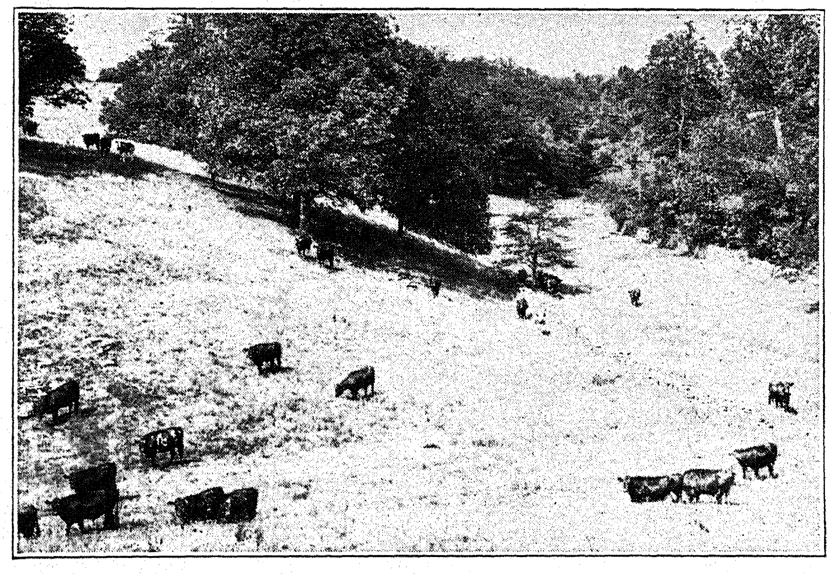
As is pointed out later in this discussion, there are certain decided ad-

vantages in finishing cattle on pasture, but also definite disadvantages. To gain much of the benefit from pasture fattening and yet avoid most of the disadvantages, pasture fattening is often combined with a relatively short finishing period in dry lot. A popular method, described later, is to graze the cattle on good pasture until midsummer, with or without the feeding of grain or other concentrates. They are then put in dry lot and full-fed on grain for 90 days or longer. (1242)

1234. Quality of beef from pasture-fattened cattle.—Experiments have proved that when cattle are equally well fattened by full-feeding grain on pasture or by fattening in dry lot, the pasture-fed cattle yield beef that is equal in palatability and tenderness to that produced by dry-lot feeding.[52] Contrary to some earlier opinions, the lean meat from cattle well fattened on pasture is no darker in color than that from cattle similarly fattened in dry lot.

When the pasture is growing luxuriantly and is high in carotene, the fat of the carcass is often a trifle yellower than in the case of cattle finished in dry lot. This yellow tinge is due to a higher carotene content of the fat, and it thus increases the vitamin value of the beef, instead of injuring it in the slightest. However, because of a prejudice in the meat trade against yellow fat, such carcasses may sell at a lower price, even though the discount is not justified.

This prejudice against yellow fat probably arose because the body fat of certain dairy breeds—Jerseys and Guernseys—is generally yellowish in color. Ex-



FATTENING CATTLE ON LAND UNSUITED FOR TILLAGE

Fattening cattle on pasture is a good way of utilizing land unsuited for tillage.

Several experiments have been conducted to compare the summer fattening of cattle in dry lot, with either full-feeding grain on pasture or with finishing the cattle in dry lot after being pastured without grain feeding for part of the season.[51] In most of these trials the feed cost of 100 lbs. gain has been decidedly less and the net return has been greater where pasture was utilized in one of these methods, than where the cattle were finished entirely in dry lot. The use of pasture in various methods of beef production is described later in this chapter.

periments indicate that if the meat is from well-fattened beef animals, a yellow tinge in the fat is not so objectionable to consumers as has been thought in the meat trade.

Cattle full-fed grain on pasture yield as high a percentage of dressed carcass as dry-lot cattle having equal finish. However, they tend to shrink a little more on shipment to market.

Cattle fattened on pasture alone, without the feeding of grain or other concentrates, generally yield carcasses of decidedly lower quality, because they are less well fattened. On account of the lack of finish, they yield a smaller percentage of dressed carcass than do well-fattened cattle, and the meat has inferior eating qualities.

1235. Advantages and disadvantages of pasture fattening.—Fattening cattle on pasture has the following advantages over dry-lot feeding: (1) Pasture gains are cheaper. This is because less grain is needed per 100 lbs. gain; because pasture is a cheaper roughage than hay or silage; and because little or no protein supplement is required. (2) Less labor is required, for the cattle need be fed only once a day, and no roughage is given. Often the grain is self-fed, still further reducing the labor. (3) The manure is well distributed on the field, and fertility is saved. (4) No shelter is required, except that shade in the pasture is highly desirable.

These advantages are more or less offset by the following disadvantages: (1) Well-fattened cattle marketed directly off pasture may sell for appreciably less per hundredweight than dry-lot-fed cattle of equal finish. (2) A farmer has less time to care for fattening cattle in summer than in winter. (3) In extremely hot weather, cattle may not make good gains, because of the heat or flies. Gains may also be checked by drouth. (4) When a permanent pasture is grazed, the manure does not benefit the fields in the regular crop rotation. (5) On pasture fields in the rotation, it may be difficult to provide water and shade.

In farming districts where much land is unsuited for tillage, the fattening of cattle on grass is common, for a maximum use is thus made of pasturage. On the other hand, on farms where there is but little untillable land, dry-lot fattening is more common, for more feed can be produced on an acre of tilled crops than on an acre of pasture.

1236. Feeding concentrates on pasture.—When cattle are fattened on pasture, no concentrates at all may be fed, a small allowance may be given during the entire pasture period, concentrates may be fed only the last few weeks, a liberal allowance may be given throughout the entire period, or the cattle may be finished in dry lot after the pasture period. In most of the experiments it has usually paid to feed some concentrates to cattle being fattened on pasture, at least during the last part of the pasture season, or else to finish them in dry lot on a full feed of grain.[53]

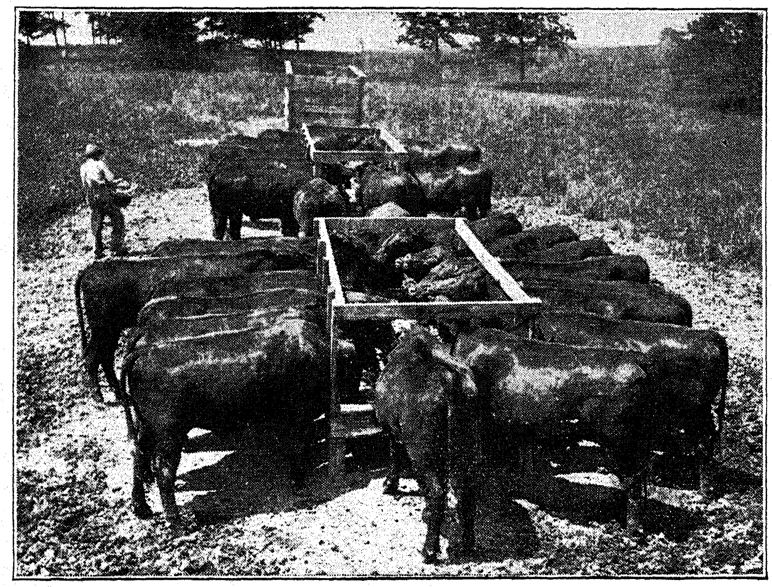
In the pasture fattening of cattle on farms, care should be taken to plan the feeding operations so as to avoid selling the cattle in late summer and fall, in competition with the large supply of grass-fat cattle from the western range. This competition may be avoided by getting cattle that are fed grain on pasture fat enough to market them before the rush of grass-fat cattle arrives. Another plan is to fatten steers of good quality sufficiently by feeding a liberal amount of grain on pasture, so that they will sell as good to choice fat steers. The prices for such cattle are usually good in late summer and early fall, due to a scanty supply.

The gains on pasture alone will commonly be cheaper than when grain is fed in addition, but the cheapness of the gains is more than offset if the cattle do not reach a good finish, and hence sell as feeders or low-grade slaughter cattle. Cattle that are 2 years old or more become much fatter on pasture alone than those that are younger, for the latter tend to grow as well as fatten. To fatten yearlings sufficiently for the large markets, it is usually necessary to feed grain in addition to pasture, or to finish them in dry lot for a short feeding period before they are marketed.

In certain districts the pasture is so nutritious that cattle 2 years old or older can be well finished on grass alone. For example, many cattle are brought from southwestern ranges for fattening without grain on the bluestem pastures of Kansas and Oklahoma. Also, many cattle are finished for market without grain on excellent bluegrass pastures, especially in certain areas from Virginia to Tennessee and Kentucky.[54]

steers being fattened on pasture will increase the gains sufficiently to be profitable, depends on the quality and stage of maturity of the pasture forage. On excellent, immature pasture, feeding a protein supplement instead of grain has generally not been profitable in several experiments.[55]

On the other hand, when grass pasture approaches maturity and is consequently lower in protein, it will pay to feed a protein supplement.[56] Also, if cattle are full-fed corn on grass pasture, containing no legumes, feeding 1 lb. of protein supplement to each 10 or 12 lbs. of corn may increase the gains enough to be profitable.[57] There is no need of a protein supplement when the forage contains a considerable proportion of legumes.



HAND-FEEDING STEERS EAR CORN ON PASTURE

It usually pays to feed some grain or other concentrates to cattle being fattened on pasture, or else to finish them in dry lot on a full feed of grain.

In the northern states the concentrate most commonly fed on pasture is corn, with perhaps a small amount of a protein supplement in addition. In the South, however, cottonseed cake or meal is often the cheapest concentrate available, and therefore an allowance of 3 to 4 lbs. per head daily is frequently fed as the only concentrate to cattle on pasture.

1237. Feeding a protein supplement with corn on pasture.—Since immature grass is rich in protein, corn and good pasture make a well-balanced ration for fattening cattle, even for calves. Whether the feeding of a protein supplement to

There is more advantage in feeding a protein supplement to cattle of high grade, that will sell near the top of the market when well finished, than to low-grade animals, which will not bring the best price, no matter how they are fed.

1238. Gains on pasture; amount eaten; area per head.—The gains of cattle fed no grain on pasture will vary widely, depending on the supply of forage throughout the season and on the nutritive value of the pasturage. On good pasture where there is an abundance of feed, yearlings should gain 1.25 to 1.50 lbs. a day for the season and 2-year-olds 1.50 to 2.00 lbs.[58] The gains are generally most rapid during the period of flush growth of pasturage in May and June and become small if the forage becomes scanty later. In the Gulf States the rate of gain is usually not over 1.0 lb. per head daily.

By digestion trials with steers on pasture, it was determined in Illinois studies that they ate as much as 35 lbs. of dry matter daily per 1,000 lbs. live weight, which made over 100 lbs. of green forage daily in some instances.[59] On 5-weeks-old bluegrass and on red clover they consumed more than twice as much forage as they needed for maintenance. Therefore, they had more than half their feed available for gain in weight.

In similar Kentucky experiments steers consumed 18.8 lbs. digestible organic matter a day on Ladino clover pasture, 11.7 lbs. on orchard grass, 10.5 lbs. on bluegrass, and only 9.0 lbs. on tall fescue.[60]

The area of pasture required per head for cattle fed no grain on pasture will range all the way from 2 acres or less per 1,000 lbs. live weight on fertile pasture in the humid districts, up to 7 to 10 acres or more on good grazing lands of the western ranges. When concentrates are fed to cattle on pasture, the area of pasture needed per head is considerably reduced.

1239. Hints on fattening cattle on pasture.—Care should always be taken in changing cattle from dry lot to pasture, especially when they are in good flesh, or else they may not continue to gain or may even shrink severely.

When cattle are turned to pasture early in the season and there is no dry grass standing over from the preceding fall, it is wise to leave them on pasture for only a short time the first day and increase the period gradually, or severe scouring may result. Because silage is laxative, if it has been fed during the winter the allowance should be reduced or entirely withdrawn as soon as the cattle are turned to pasture. If grain has been fed during the winter, it should be continued until the cattle are accustomed to grass.

If the pasture forage is very young and succulent, supplying some hay in a rack may reduce scouring the first few weeks, and increase the gains.[61]

Supplying cattle on pasture with salt, shade, and plenty of good water should never be overlooked. In regions where horn flies or other flies are serious pests, the gains of cattle on pasture are decidedly increased when they are sprayed with a wettable DDT preparation.

Cattle that have been fed a fairly liberal allowance of grain or other concentrates during the winter and that are fully half fat at the beginning of the pasture season, had best be finished in the dry lot. If they are turned to pasture, they will usually make poor and expensive gains during the first month or so.[62]

When feeder cattle are purchased early in the fall for fattening in dry lot during winter, some cheap gains can often be secured by grazing them on pasture for a few weeks before starting the dry-lot feeding. It has been mentioned in Chapter XX that cattle are sometimes turned into standing corn in the fall to harvest the crop, pigs following the cattle to get the corn not eaten by the cattle. (697)

IV. Methods and Costs of Beef Production

1240. Various methods of beef production.—Several efficient methods of beef production are followed in various parts of the United States. At one extreme is the production of heavy, fat calves, which are marketed when only 7 to 10 months of age. Next comes the production of baby beeves and fat yearlings, then the fattening of yearling

feeder cattle, and last the fattening of cattle 2 years old or more when placed on feed.

1241. Production of fat slaughter calves.—The production of fat slaughter calves is a rather recent development, brought about by the demand from consumers for light-weight carcasses that will furnish small cuts of tender beef with very little waste. These calves are often called "super" or "ultra" baby beeves, but these terms are somewhat misleading, as they imply that the carcasses of such animals are superior to baby beef. On the contrary, the beef from these calves, marketed when only 7 to 10 months old and weighing but 500 to 700 lbs., lacks the color and flavor of beef from older animals. It is lighter in color, being slightly like veal. Nevertheless, it is tender and is well liked by many people.

In this method the cows generally calve in the fall or early winter. The suckling calves are commonly creep-fed and are marketed directly off the cows from May to November, depending on their age.[63] Late calves can be weaned and fattened for 60 to 90 days.

This method is especially well adapted to the southern states, where much of the winter feed for cows and calves can come from special temporary pastures. With proper feeding, plain cows and those with some dairy blood will produce slaughter calves which will grade Choice, if bred to a good beef bull. The part dairy blood may actually be a benefit in this type of beef production, as the cows give more milk. If such calves are fattened for market when older, they will generally grade lower, because the defects in their ancestry will be apparent.

1242. Baby beef production.—Next in age at which the cattle are marketed, comes baby beef production. Under this system well-bred beef calves are so fed that they are well fattened and ready for market when 10 to 15 months of age and weighing 650 to 850 lbs. Such cattle are also classified as fat yearlings.

The carcasses provide popular-sized cuts of beef, and the meat is tender and satisfactory in taste, although not so rich in flavor as that from older cattle.[64] If the calves are well fattened, the carcasses will have a good covering of fat and the meat will have a sufficient degree of marbling. To produce meat of satisfactory quality, baby beeves need not be carried to a wasteful degree of fattening, because the lean meat is more tender than that of older animals.

Baby beef production requires, first of all, well-bred beef calves that will develop into high-grade fat cattle at an early age. Also, calves intended for baby beef must be fed liberally on grain and other concentrates. Otherwise, they will merely grow instead of fattening. This method is therefore not suited to farms where beef is produced primarily to utilize roughage. It is especially adapted to corn-belt farms where corn is cheaper than in other sections and the only pasture may be on arable, high-priced land.

Baby beef production is best suited to the farmer with a good beef herd who raises his own calves. He can be sure of having thrifty calves of the proper type for this intensive system.

In producing baby beef, the cows are fed and cared for much the same as in the more common types of beef production. They are often fed a little more liberally to ensure a good milk flow, but they must be maintained economically, or profits will be eaten up.

The calves are usually dropped in early spring and run with their dams on pasture. While on pasture, the calves are often fed grain or a concentrate mixture in a creep, at least during the latter part of the summer if pastures are short. They are then accustomed to grain at weaning time and suffer no setback. The object is to retain the "calf fat" and fatten the calves as they grow.

Calves that are in good condition in the fall at weaning time and which are full-fed on a proper ration should be ready for market from May to August, after most of the older fat cattle from the feed lots of the corn belt and other districts have been marketed. Steer calves must usually be fattened for 200 days or longer after weaning, to reach the desired finish. Heifers can generally be

made fat enough in 160 to 170 days, and bring the best price when marketed at a weight of about 750 lbs. or less. Even though pasture is available in the spring, it is best to continue fattening the calves in dry lot, instead of turning them to pasture.

When western range calves are bought on the market to be fattened for baby beef, they will not usually carry as much fat as home-raised calves. However, if they are thrifty, well-bred, and of good quality, they can be fattened on a liberal allowance of grain.[65] Care must be taken to feed a protein supplement when one is needed to balance the ration, for calves need a larger proportion of protein than do older cattle. (1163)

The amounts of feed consumed and the gains made by calves fattened for baby beef are stated in a previous article. (1195) It is there shown that calves require considerably less feed for 100 lbs. gain than older cattle, and therefore make cheaper gains.

A BEEF HERD ON A CORN BELT FARM

The calves from these well-bred cows are creep-fed on pasture and then fattened on a full feed of grain for marketing as baby beeves.

satisfactorily for baby beef by feeding them good rations, though they will not be ready for market at as early an age as calves fed liberally at all times.

Unless grain is unusually high in price in comparison with other feeds, calves being fattened for baby beef should be brought to a full feed of grain as soon as possible and should be fed liberally throughout the fattening period. When grain is extremely expensive compared to roughage, it may be most profitable to feed the calves chiefly on good roughage during the first half of the feeding period, and then finish them

1243. Finishing cattle as fat yearlings.—On farms where an important object in beef production is the utilization of pasture and harvested roughages, the finishing of cattle somewhat later as fat yearlings offers marked advantages over baby beef production. The cattle are handled according to various methods, the choice depending on local conditions. Several experiments show that the following methods all give excellent results.[66]

Where the desire is to use the maximum amount of roughage, the calves are wintered so they will gain 1.0 lb. per

head daily or slightly more. As shown previously, this will require only good roughage, such as corn or sorghum silage, with 3 to 5 lbs. of legume hay or else 1 lb. per head daily of protein supplement to balance the ration. (**1221**)

During the pasture season they are grazed, without grain feeding, on good pasture. In midsummer or towards fall, they are put in a dry lot and full-fed on grain and good roughage for 90 days or longer, until they are fat enough to meet the market demands. Under this method the cattle are marketed in late fall or early winter, before the rush comes on the market of fat older cattle from the feed lots.

In a series of New York experiments this method of handling feeder calves purchased in the fall was the most profitable.[67] These steers required about 500 lbs. less corn per head to reach approximately the same carcass grade as steers full-fed entirely in dry lot. They served as a market for about twice as much hay and corn silage, utilized 100 days of pasture during the flush pasture seasons, and made an appreciably greater net return above cost of feeder calves and feed.

In another method, steer calves of high quality are wintered similarly on roughage and then full-fed grain on pasture until fat. They should be ready for market from August to November, at the time when there is an over supply of half-fat, grass-fed cattle from the ranges and other grazing districts, but a shortage of well-finished fat cattle of good quality.

If it seems best to have the cattle ready for market somewhat earlier, the calves should receive a limited amount of grain during the winter (3 to 5 lbs. per head daily) in addition to good roughage and also a protein supplement, if the latter is needed. They can then be finished by full-feeding grain on pasture for 75 to 120 days, the length of time depending on their condition in the spring and on the degree of fatness in demand on the market. Such cattle can be classed as baby beeves.

Except perhaps when the pasturage is unusually nutritious and abundant, it is not advisable to graze the cattle without grain in summer, if they have been wintered on considerable grain with good roughage. They will then usually be too fleshy in the spring to do well on grass alone.

When the cattle are of such quality that they will grade choice to prime when finished sufficiently well, it may be best to feed them in dry lot for at least 4 to 6 weeks, before marketing. This will not only improve their actual condition slightly but will also better their appearance still more, for it will help to overcome the sunburned appearance of the coats of pasture-fed cattle. Since some buyers still have a prejudice against cattle fattened on pasture, this change in looks will usually increase the selling price.

Instead of turning the cattle on pasture in the spring, some prefer to full-feed them in dry lot during spring and summer, until they are ready for market. This may increase the selling price over pasture-fed cattle, but it requires much more labor and it increases the feed cost per 100 lbs. gain. In most of the experiments in which this method has been compared with others, it has given a lower net return than when pasture was used.

1244. Finishing cattle as 2-year-olds or older.—Where pasturage and roughage are cheap and abundant, cattle are often not finished for market until 2 years old or older. When cattle are to be fattened during their second winter, they are generally fed during the first winter on roughage alone, or roughage plus 1 lb. per head daily of protein supplement or 2 to 3 lbs. of grain. (**1221**) They are then pastured without grain feeding during the summer and put into the feed lot for fattening at the close of the pasture season.

Such yearlings can be well fattened in 100 to 160 days, if they come off the pasture in good condition. Weighing 600 to 750 lbs. when placed on feed, they are generally fat at weights of 950 to 1,100 lbs. when about 2 years old, and

meet the market demand for well-finished light-weight fat cattle.

In another method cattle are carried through their second winter chiefly on roughage, and either fattened on grass the next summer, with or without grain feeding, or else fattened in dry lot.[68] Kentucky experiments have shown that it is better to feed grain on grass than to use the same amount of grain in carrying the cattle through the previous winter, and then pasture them during the summer without grain feeding.[69]

Still other cattle are put into the feed lot as 2-year-old feeders in the fall and fattened for sale the following spring when approaching 3 years of age. The results that can be expected from fattening yearlings and 2-year-olds, in comparison with calves, are shown in the preceding chapter. (**1195**) A few cattle are still carried through 3 winters before they are fattened. However, such cattle are too heavy when fat to meet present-day demands, and therefore they have practically disappeared from the large central markets.

1245. Fattening range cows.—The purchase and fattening for the market of range cows which have been discarded on account of age or for other reasons is a hazardous undertaking. Experiments have shown that the gains made by such cows are generally very expensive.[70] Also, many prove to be so far advanced in pregnancy that they must be kept over and fattened for market after they have raised calves. In addition, there is danger of introducing brucellosis or other diseases unless such cows are carefully isolated from other breeding cattle.

1246. Fitting cattle for shows or sale.—In order to win in the show ring, both fat steers and breeding cattle must be in a high state of finish. While this degree of fatness may be detrimental to the future usefulness of bulls or cows, one cannot hope to win under present standards unless the cattle are thoroughly fat. Cattle in high condition also commonly bring a better price in a sale.

Consequently, in fitting cattle for shows or for a sale, they must be fed a very liberal amount of concentrates and a relatively small amount of roughage.[71] The economy of the ration is of relatively little importance, compared to the degree of finish that is reached.

Four to eight months are usually needed to bring cattle from thrifty breeding condition to show condition. Therefore, fitting must start early enough to accomplish the desired result.

A highly palatable concentrate mixture should be fed, in order to induce maximum consumption. For this reason, many showmen prefer mixtures containing molasses. Wheat bran is a common ingredient of mixtures for fitting cattle, due to its palatability and its mild laxative effect. Linseed meal is a favorite protein supplement, because it tends to produce a glossy coat and also because of its conditioning effect. Cattle being fitted are generally fed 3 or 4 times a day, so as to secure maximum feed consumption.

The following concentrate mixtures are recommended by Snapp for fitting cattle: [72]

1. Ground corn, 50 lbs.; crushed oats, 25 lbs.; wheat bran, 15 lbs.; and linseed meal, 10 lbs. Each feeding should be moistened with one-half pint of molasses, diluted with an equal volume of water.

2. Crushed barley, 40 lbs.; crushed oats, 25 lbs.; wheat bran, 10 lbs.; and molasses feed, 25 lbs.

3. Shelled corn, 50 lbs.; whole oats, 20 lbs.; linseed meal, 10 lbs.; and molasses feed, 20 lbs.

In order to insure maximum gains, the cattle must be comfortable. In summer they should be kept in a well-ventilated barn, except that it is desirable to turn them on good grass pasture at night. This provides exercise, as well as succulent feed. Exposure to hot sun makes their hair dry and stiff. Effective measures should be taken to control flies.

1247. Beef cattle production on the range.—About three-fourths of the beef breeding cattle in the United States are in the western states and in the great plains district from North Dakota to Texas. Here they are mostly kept under range conditions. Range beef cattle pro-

duction is also important in certain districts of Florida and other southern states.

The methods used in beef cattle production on the range differ considerably in various regions.[73] In some range sections, as in parts of Texas, the grazing land is privately owned and generally fenced. On the other hand, in the mountainous districts of the West much of the grazing is in the National Forests and on the public lands.

In the early days of the western ranges little effort was made to provide harvested feed to carry cattle through the winter. Therefore, the losses of stock by starvation were sometimes appalling in winters with heavy snowfall. Now most western ranchers have some land on which hay or other crops are raised for winter feed. In the mountain districts the cattle are commonly wintered on range land at lower elevations, adjacent to the ranch headquarters. The feeding of harvested feeds is delayed as long as possible in the autumn or winter, so the cattle will get as much of their living as they can from the winter range.

Spring calving is general in range herds, the date depending on the system of management and the climate. Occasionally, sheds are provided for shelter and the cows are bred for early spring calving, so that the calves will be heavier in the fall.

In the western mountainous regions the cattle graze in spring on the lower foothills, and then as the season advances they go to the more elevated and more rugged areas. By the end of June they are usually on this summer range, where the forage remains green and palatable until late in the season. In the fall they are brought back to the spring range.

The cattle are looked after by experienced riders or herders who see that they are kept on good grazing areas, and away from areas infested with poisonous plants. These men also provide salt at proper salting grounds and prevent the cattle from straying. The various ranchers grazing cattle in a given district usually cooperate in the spring and fall round-ups.

In the spring round-up the cattle belonging to each ranch are identified by means of the brand and are counted. The calves are branded and castrated, and also the breeding cattle are sometimes separated from the steers and yearling heifers. In the fall round-up, which takes place in September or October, the cattle to be sold are sorted out, and any calves are branded that have been dropped since the spring round-up.

Generally, the percentage calf crop is considerably smaller in range herds than under farm conditions. In the northern range districts the number of calves weaned per 100 cows bred usually does not average more than 65, and in the semi-desert range areas of the Southwest the number is even less. The calf crop is often seriously lessened by a lack of suitable feed for the cows in winter, by an inadequate supply of bulls or poor condition of the bulls, and by permitting heifers that have not been well fed to be bred to calve when only 2 years old.

The results secured at the United States Range Livestock Experiment Station in Montana show how the calf crop can be increased under good systems of range management and with proper culling of the breeding herd.[74] For a period of 18 years, including 4,753 cow years, an average of 81 calves were weaned per 100 cows in the herd. The importance of managing the grazing so as to maintain and increase the productivity of the range has been emphasized in Chapter XVIII. (385)

1248. Costs of beef production.—Cost accounting surveys conducted several years ago on corn-belt farms by the United States Department of Agriculture furnish the most extensive information that is available concerning the amounts of feed required by beef cattle, and other costs of beef production.[75] These studies, which are summarized in the following table, represent averages for 11,261 beef cows handled according to usual methods, 4,572 beef cows kept for baby beef production, 7,236 beef calves carried through the winter for later fattening, and 4,009 calves fattened for baby beef.

It will be noted that the cows were maintained almost entirely on roughage, the first group of cows being fed only 67 lbs. of grain per head annually, and the cows kept for baby beef production only 140 lbs. (Any protein supplement fed to the cows was reduced to grain equivalent.) Only 15.3 hours of man labor and 10.4 hours of horse labor per head were required per cow a year for the cows kept for ordinary beef production.

The costs of feed and labor, using local prices at any time, can be estimated from these data. After allowing credit for the value of the manure produced, the cost of feed and labor usually is 80 per cent or more of the total net cost in beef production in an enterprise of good size.

In these herds the percentage calf crop raised to weaning time was 85. This means that 85 calves were raised per 100 cows. To find the cow cost per calf raised, the estimated net cost per cow must therefore be divided by this percentage. To this must be added a charge for bull service.

In these studies data were also secured on cows in dual-purpose herds which were partially milked. Because of the credit for the milk sold, the cost per calf at weaning time was less in these herds. However, the calves were undoubtedly not so heavy or fleshy, or otherwise desirable as in the herds which were kept strictly for beef production.

1249. Cost of fattening cattle.—The cost of fattening cattle will vary widely in different sections of the country and at various times. The chief items of cost are the initial cost of the feeder cattle and the cost of the feed. Other expenses are man labor, tractor or horse labor, building and equipment charges, interest, mortality risk, veterinary services, insurance, taxes, marketing costs, and incidental expenses.

Feed and labor required for beef cows and calves

	Usual methods of beef production		Baby beef production	
	Maintaining cows per year	Wintering calves	Maintaining cows per year	Fattening calves
Feed per head				
Pasture, days	194	9	197	48
Hay, lbs.	1,900	1,218	1,940	1,150
Silage, lbs.	700	266	740	658
Straw, lbs.	660	110	500	40
Fodder, lbs.	. .	159	. .	. .
Corn or other grain, lbs.	67	482	140	2,296
Protein supplement, lbs.	. .	. .	7	141
Corn stalks, acres	1.4	0.1	2.0	0.03
Labor per head				
Man hours	15.3	8.6	16.7	12.2
Horse hours	10.4	6.8	9.6	9.1

The cost of the feed will generally form 70 to 80 per cent or more of the operating expenses, not including the initial cost of the cattle or the expenses of marketing them. It is often assumed that when cattle are full-fed on shelled corn or ear corn, the by-products of fattening operations (the manure secured and the pork produced by the pigs following the cattle) will usually pay for all farm costs other than the initial costs of the cattle and the cost of the feed.[76] However, to get this result, losses of fertilizing value in the manure must be avoided and labor cost must be reduced by efficient planning and equipment.

It must be borne in mind that when cattle are fattened in winter on a general farm, most of the labor comes at a time of the year when it might not otherwise

be utilized. Therefore much of it does not represent any real additional expense.

In an extensive survey of the fattening of beef cattle on farms in Indiana, Illinois, Iowa, Nebraska, and Missouri (including data on 34,934 cattle), the United States Department of Agriculture found that on the average the cattle weighed 786 lbs. when placed on feed, were fed for 174 days, and made daily gains of 1.63 lbs. and an average total gain of 284 lbs. during the feeding period.[77] For each 100 lbs. gain there were required 680 lbs. grain (chiefly corn), 62 lbs. commercial concentrates (chiefly protein supplements), 391 lbs. hay and other dry roughage, 863 lbs. silage, and 20 days of pasturage.

1250. Reducing the cost of beef production.—Even under the same general conditions, there is often a great difference in the cost of producing beef cattle on individual farms. For example, in a study of methods of wintering beef cows on corn-belt farms by the United States Department of Agriculture, it was found that on some farms the cost was twice as high as on others.[78] This was due largely to a failure to use cheap roughages in wintering the cows. Many farmers were overfeeding their cows and hence wasting feed, without securing any better calves. One of the greatest wastes was found to be the feeding of unhusked corn fodder, in place of husking out the corn for other stock and feeding the cows the stover, after cutting or shredding it.

Pasture improvement and fertilization and the utilization of pasture over a long season are essential to produce beef at minimum expense. Full use should always be made of the cheap feed furnished by grazing on stalk and stubble fields and the aftermath of meadows.

Another important factor in reducing the cost of producing beef cattle is to build up, by selection, a herd of cows which are all regular breeders and satisfactory mothers, producing plenty of milk for their calves.

Much labor can be saved and the amount of hard work greatly reduced by efficient equipment and good planning in the storage and handling of feed and in stabling arrangements. For example, in Illinois studies on corn-belt farms, the amount of time spent in feeding, per ton of feed, ranged from 35 minutes to a low of less than 10 minutes per ton.[79] The travel per ton of feed varied from a high of 11,300 ft. down to 273 ft. for the most efficient arrangements.

From these and other studies the following ways in which time and labor can be saved were emphasized:

1. Haul silage in carts or in cars moved over rails, instead of carrying it in baskets.
2. Use self-feeders built into the mow floor for feeding chopped hay.
3. Use self-feeders instead of feeding by hand.
4. Use blower pipe to move feed from grinder to feeder.
5. Have feedlots near the feed-storage buildings.
6. Provide hopper-bottom bins, drag conveyors, and elevators in cribs and granaries.
7. Provide better chore routes for trucks and wagons by replanning barnyards and fences.

By use of a hydraulic manure loader, the most disagreeable work can be largely avoided and much time can be saved.

V. Counsel in the Feed Lot

1251. Cattle fattening requires business judgment.—Even more than in other types of livestock farming, the fattening of purchased feeder cattle requires sound business judgment, or the venture is apt to result in loss. This is because it is a much more speculative enterprise than most ventures in animal husbandry. To secure good profits it is therefore especially necessary that the several factors which make for success be kept clearly in mind.

Before buying feeder cattle, one should estimate the quantity of feed on hand and determine how many and what class of cattle he had best buy to consume the feed. From a study of market reports he can estimate how much his feeders will cost, including the cost of

getting them to his feed lot. He can figure out approximately how much the gains will cost him, by using data like that given in this and the preceding chapter. He can then estimate the necessary selling price he must secure to break even, considering the marketing costs. If the outlook for a profit does not seem reasonably good, it is usually best not to buy just at that time.

The kind of feeder cattle should always be chosen which will probably offer the best opportunity for profit at the particular time. The summaries presented previously show the results that can be expected from various grades of feeders and from calves, yearlings, and 2-year-olds. (**1195–1197**) It is an old adage among stockmen that "cattle bought right are more than half sold." A man may be a skillful feeder and lose money year after year because of poor judgment in buying.

The beginner should hire an experienced cattleman to purchase animals that will best suit his needs, or deal with a reliable commission firm that is acquainted with his conditions. If choice feeders are commanding a high premium in the market over lower grades, and it does not seem probable that the premium will be correspondingly large for the cattle of better quality when they are fattened, a lower grade had better be purchased.

By following the various market reports for preceding years one can tell approximately at what time of year his cattle can be marketed to greatest advantage. They should then be fed so as to be finished at that time. It has been emphasized in the previous chapter that the cattle should be fattened only enough to return the greatest profit under the particular market conditions. (**1198**) It is much more important to secure a good net return than it is to "top the market."

When the cattle are ready for market, it is usually not advisable to hold them for better prices, unless they continue to make gains at a reasonable cost. The extra feed consumed by finished cattle will soon more than offset any ordinary increase in price that may be obtained. When the cattle are almost finished, the owner should watch the market reports and find out from his commission firm what they consider the best date for shipment.

1252. Rations for fattening cattle.—The experiments reviewed in the preceding chapter show that much greater profits are secured when fattening cattle are fed properly-balanced rations. Whenever there is any question as to whether a ration is balanced, it will take but a short time to compute the approximate amounts of dry matter, digestible protein, and total digestible nutrients it contains, and see how closely the ration meets the recommendations of modern feeding standards (Appendix Table III). The time it takes to work out suitable and economical balanced rations is commonly the most profitably spent of all the year. Example rations suited to various conditions are given in Appendix Table VII.

To determine which of the several available feeds are actually the most economical, one should refer to the detailed discussions of the various feeds which are given in the chapters of Part II of this volume. Definite information is there presented concerning the relative value for beef cattle of all the more important feeds.

1253. Equipment for feeding cattle.—It has been emphasized previously that much labor can be saved and the amount of hard work reduced by efficient storage and handling of feed, good stabling arrangements, and the use of a hydraulic manure loader in cleaning stables and yards. (**1250**)

The shelter requirements for beef cattle under various climatic conditions have been discussed in the previous chapter. (**1204**) Where the soil and climate are such that the feed lots often become seas of mud in winter or early spring, paving them with concrete is an economy. Not only do the steers make larger and more economical gains, but also much loss of manure is prevented. (**1206**)

Cattle of the same age, or at least those of equal size and strength, should

be fed in the same lot. From 2.5 to 3 feet of feed racks or bunks should be provided per steer, so there will not be undue crowding at meal time. Some feeders use combination feed racks for grain and roughage, while others prefer a separate rack for hay and a bunk or flat manger for silage and grain. Feed racks and bunks should always be cleaned after each feeding. Salt and fresh water should always be provided beef cattle. (1169, 1181)

1254. Getting cattle on feed.—Cattle that are not accustomed to grain or other concentrates must be started on feed gradually, or serious digestive trouble may result. When feeder cattle are first brought to the feed lot, it is best to restrict the amount of hay or other roughage slightly for a day or so, until they have recovered from the effects of their trip.

They should then be started on grain. A safe plan is to feed calves not more than 1 lb. of grain per head at the first feed, or 2 lbs. for the day. Older cattle may be started on a little more grain. The allowance may be gradually increased at the rate of about one-half pound per head daily or less, care being taken not to increase the amount unless the cattle are eager for each feed and clean up the grain properly.

If they wish to get cattle on a full feed of grain as soon as possible, experienced men may increase the allowance of grain as much as 1 lb. per head daily. When cattle are approaching a full feed, the increase should be very gradual.

If a protein supplement is to be fed to balance the ration, it is best to feed no more than one-quarter to one-half pound per head daily at first and then gradually increase the amount at the rate of one-quarter pound per head daily until the full amount needed to balance the ration is supplied.

1255. Frequency and order of feeding.—Most cattlemen feed concentrates and roughage twice a day to fattening cattle not on pasture. Often cattle being fitted for shows are fed grain more frequently, so as to induce them to consume a larger amount.

The feeding should always be at the same time each day. The cattle should not be disturbed until after daylight, and they should have time to clean up the evening feed before dark. Usually, the concentrates are fed first and then the silage is put in the feed bunk, if this excellent feed is being used. Hay or other dry roughage is fed in suitable racks, also twice daily as a rule. However, if two kinds of roughage are fed, sometimes one is fed in the morning and the other at the evening feed. In this case, the less palatable roughage should be fed in the morning. So that each animal can get its share of protein supplement, such as linseed meal or cottonseed meal, it should be mixed with the grain or else distributed over the silage.

Though cattle being fattened in dry lot are usually fed twice a day, in Tennessee and Wisconsin trials the gains were as rapid when both grain and roughage were fed only once a day.[80]

When cattle are given grain or other concentrates on pasture, they are commonly fed but once a day. This is largely as a matter of convenience, for they may be grazing on a pasture at some distance from the farmstead.

1256. The eye of the master fattens his cattle.—There is so much truth in the old adage, "The eye of the master fattens his cattle," that every stockman should bear it in mind. Being versed in the science of stock feeding is not enough for success. To secure the greatest profits, not only must one feed his stock economical and well-balanced rations, but also he must have the watchful eye and good judgment of a true stockman. The best results are obtained only when the cattle are fed at regular hours, and when the attendant is quiet and kind at all times, so that the animals trust rather than fear him.

Experience counts for much in stock feeding. Many an experienced stockman can carry steers through the fattening period without getting them once "off feed," but yet cannot well describe to others just why he is so successful. In general, when steers are to be full-fed on grain, they should be supplied all they

will readily consume at each feeding, after they have been gradually brought onto feed. Any feed left in the feed bunk or manger should be cleaned out before the next feeding, for it will not usually be eaten by the cattle afterwards, but will spoil and contaminate the fresh feed put in later.

Scouring, the bane of the stock feeder, should be carefully avoided, since in a single day it may cut off a week's gain. This trouble is generally brought on by overfeeding, by unwholesome food, or by a faulty ration. Overfeeding comes from a desire of the attendant to push his cattle to better gains, or from carelessness and irregularity in measuring out the feed supply. When cattle are fattened on alfalfa hay and barley or wheat grain, care must be taken to avoid trouble from bloat. (**49**)

The droppings of the steers are an excellent index of the progress of fattening. While they should never be hard, they should still be thick enough to "pile up" and have that oily appearance which indicates a thrifty condition. There is an odor from the droppings of thrifty, well-fed steers known and quickly recognized by every good feeder. Thin droppings and those with a sour smell indicate something is wrong in the feed yard.

1257. Pigs following fattening cattle.—When fattening cattle are fed ear corn, shelled corn, or corn silage, pigs should be kept with them to utilize the unchewed and undigested corn in the droppings. Frequently, the margin in cattle fattening is so narrow that the gains made by the pigs form the larger part of any profit from the feeding operation. When cattle are fattened on such a ration as ground grain and hay, without corn silage, or on cottonseed meal and cottonseed hulls or hay, there is no need of having pigs in the feed lot, for they could not secure much of any waste feed.

The number of pigs per steer varies with the kind of feed and the age of the cattle being fed. For cattle full-fed on the common corn-belt ration of shelled corn, corn silage, legume hay, and a small amount of protein supplement, 1 pig will be needed for approximately 1 to 2 steers in the case of 2-year-olds, 1 pig to 2 steers with yearlings, and 1 pig to each 3 calves. When ear corn or snapped corn is fed, the wastage of corn by the steers is greater, and twice as many pigs may be required. In the case of ground corn or corn-and-cob meal, only one-half to one-third as many pigs are needed as with shelled corn.

The best pigs for following cattle weigh from 50 to 150 lbs., and when they become fat they should be replaced. Pigs following steers should be fed 0.2 to 0.3 lb. per head daily of tankage or similar protein supplement to balance the ration. Any extra grain given the pigs to ensure their making satisfactory gains should be fed in adjacent separate pens before the cattle are fed, so that the pigs will not crowd around the feed troughs or under the truck or wagon while the cattle are being fed.

In Iowa experiments the amount of feed saved by pigs from the droppings of cattle full-fed on shelled corn was estimated by feeding similar pigs separately.[81] It was found that for 53 separate lots of fattening cattle, the average pig, following 1.9 steers, recovered the equivalent of 312 lbs. of corn during an average feeding period of 120 days. On the average, 4.7 per cent of the cost of the feed given to the steers was saved by the pigs.

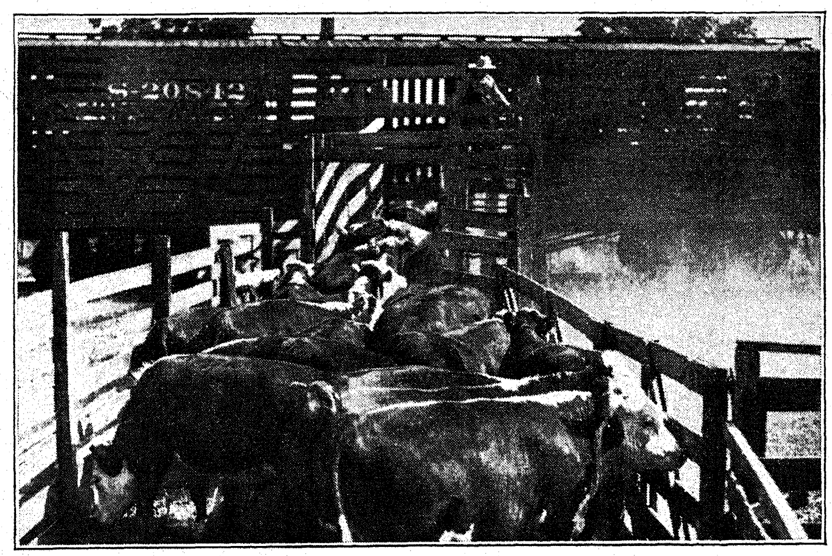
From a study of the results of many experiments, Snapp estimated that, on the average, pigs following cattle fed shelled corn would make approximately the following amounts of gain per bushel of corn fed the cattle:[82] Two-year-old cattle, 1.58 lbs.; yearlings, 1.01 lbs.; calves, 0.76 lb.

1258. Shipping; shrinkage; dressing percentage.—The shrinkage of fat cattle during shipment can be reduced to a minimum by proper handling before shipment and by care in loading. The cattle should be handled quietly and should never be driven faster than a slow walk. If they are hurried, they will begin to scour and will shrink unduly. The car should be cleaned, if necessary, and to prevent slipping should be bedded with sand, containing no stones. In cold

weather this should be covered with straw. If different kinds of livestock are put in the car, they should be separated securely. Any bulls should be tied safely in car or truck, so they cannot injure other animals.

The livestock industry suffers a heavy loss, estimated at over $27,000,000 a year, from bruised animals, because the bruises must be trimmed out of the carcasses.[83] Important ways of reducing this loss are the points that have been supplied at the last feeding should be reduced, since cattle travel better when not too full.

Silage-fed cattle show a larger gross shrinkage but usually fill so well at market that the net shrinkage is even lower than with cattle fed no silage. Cattle that have come off succulent pasture usually shrink more than those which have been fattened in dry lot. Cattle fattened on wet beet pulp shrink more than any other class.



LOADING FAT CATTLE FOR SHIPMENT

The shrinkage of fat cattle on shipment to market can be reduced by proper handling before shipment and by care in loading.

mentioned and also the following: Dehorning; removing projecting nails, splinters, or broken boards from fences, racks, trucks, and cars; keeping old machinery out of feed lots; using good loading chutes, which are not too steep; loading slowly; and using canvas slappers instead of whips, canes, or sticks.

There is probably little or no advantage in making decided changes in the ration previous to shipment, even if the cattle have been receiving silage. If very laxative feeds have been used during fattening, such as pea-green alfalfa hay, it is wise to reduce the amount the day before shipment. Also, the amounts

Some have advised changing cattle that have been full-fed a laxative ration, such as grain with silage and good legume hay, to such a ration as grass hay and a small amount of oats a day or two before shipment. This may apparently reduce the shrinkage to market, but the reduction is usually merely the result of the previous loss in weight when the change was made in the ration.

It is a mistake to withhold salt from the cattle for a few days, and then salt them liberally just before shipment, so that they will take on a large fill of water at the stockyards. If this is done, the cattle will generally scour in transit, shrink

heavily, and arrive in poor shape. Buyers both of fat cattle and of feeder cattle can recognize animals which have taken on an abnormal fill, and they discriminate against them by offering a lower price per hundredweight.

When cattle reach the market just before being sold, the fill is small, but when they arrive about daylight of the sale day, or the afternoon of the day before, they generally take a good fill.

The shrinkage between the loading weights and the sale weights at the stockyards, after feed and water, of either feeder cattle or fat cattle in transit 36 hours or less is usually about 3 to 5 per cent; when in transit 70 hours or over, the shrinkage is 5 to 6 per cent of their live weight and sometimes more.[84] In addition, there will be a slight shrinkage in weight from the feed lot to the loading station.

Well-fattened cattle shrink a smaller percentage of their live weight than those that are not so fat. For example, the percentage shrink of feeder cattle is higher than for the same animals shipped the same distance after fattening. Calves that are well-fattened have no higher percentage shrinkage than older fat animals. In 10 comparisons steer calves shrank 3.2 per cent on the average; yearling steers, 3.5 per cent; and 2-year-olds, 3.6 per cent.[85]

Good to choice fat steers will range from 56 to 59 per cent in dressing percentage, and show steers, which are of extra good type and in high condition, will usually dress 59 to 63 per cent. Fat cows dress about 56 per cent, and canners from 35 to 43 per cent.

VI. Veal Production

1259. Veal production.—Only dairy calves are commonly fattened for veal, because a better return is secured from beef calves when they are raised for beef. For the highest grade of veal, calves must be liberally fed for several weeks on whole milk as the chief or only feed. Otherwise, the carcasses may not have a sufficient degree of fatness, combined with the desired light-colored flesh and white fat.

In a recent Wisconsin trial, the addition of an iron and copper supplement to the milk to prevent possible anemia, was detrimental, because it produced pinker flesh, instead of the desired light color.[86]

Calves fattened for veal on whole milk alone for 30 to 50 days require 9 to 10 lbs. of milk per pound of gain in live weight.[87] Holstein calves fed liberally on whole milk should gain 1.8 to 2.0 lbs. a day, and calves of the smaller breeds somewhat less.

In the intensive market-milk districts, dairy calves are commonly sold for veal when only a few days old. While they would bring a considerably higher price per hundredweight if carried on milk for a longer time, this is not profitable unless the price of milk is low.[88]

Most of the well-finished veal is therefore produced in less intensive dairy regions, where a lower price is received for whole milk. Calves weighing less than 140 lbs. usually bring a decidedly lower price per hundredweight than those carried to this weight.

The gains are usually more rapid when a calf nurses a cow than if it is fed a liberal amount of whole milk. However, a recent Tennessee trial with identical twin heifers indicates that a cow which nurses her calf for several weeks produces less total milk during the lactation, even if she is stripped out after the calf nurses.[89] This lessened milk yield, which averaged 317 lbs. in this study, should therefore be included in the cost of producing the well-fattened veal calf.

Sometimes calves being fed for veal are changed from whole milk to skimmilk at 2 to 3 weeks of age and then fed skimmilk with a grain mixture and good hay, much the same as in the skimmilk-method of raising calves. Though calves thus fed make good growth, they do not lay on much fat and therefore bring a much lower price per hundredweight than calves fed plenty of whole milk.[90]

Illinois and Ohio trials indicate that the finish of veal calves fed skimmilk or reconstituted skimmilk can be improved considerably by adding a special milk-fat substitute to the skimmilk.[91] Also, the

rate of gain is generally increased by adding an antibiotic feed supplement to the skimmilk.[92] (1121)

For feeding with skimmilk, such a mixture as one-half corn and one-half oats produces as good results as a more complex mixture higher in protein.[93] (1131)

QUESTIONS

1. Why is pasture the foundation of economical beef production?
2. Describe the usual methods of feeding beef breeding cows throughout the year, when they are kept solely for beef production.
3. Discuss the nutrient requirements of beef cows.
4. State 3 satisfactory rations for wintering beef cows.
5. How are beef cows wintered in range areas?
6. How does the feeding of dual-purpose cows differ from that of cows kept solely for raising calves for beef?
7. What are the most important points in the feed and care of the beef bull?
8. What are the advantages of having beef calves born in the spring?
9. Under what conditions is it profitable to creep-feed suckling calves?
10. Discuss the feeding of beef calves being carried over the winter, stating the amount of gain that should be made under various conditions.
11. What sort of rations should be used for wintering yearlings and older stocker cattle?
12. Discuss the raising of beef heifers, including the age at which they should drop their first calves.
13. State a typical ration fed to fattening calves in your region.
14. What quality of beef is secured from pasture-fattened cattle?
15. Give the advantages and disadvantages of pasture fattening.
16. Discuss the feeding of concentrates to cattle being fattened on pasture.
17. Should a protein supplement be fed with corn on pasture?
18. About how many pounds of gain do cattle make on pasture alone during the grazing season in your region?
19. Describe the following methods of beef production: (a) Production of heavy fat calves; (b) production of baby beef; (c) production of fat yearlings; (d) fattening cattle 2 years old or older; (e) fattening old range cows.
20. Describe a method of feeding and management common on the western ranges.
21. Discuss briefly the feed and labor required for beef cows and calves.
22. Why is good business judgment especially necessary in the fattening of purchased feeder cattle?
23. What equipment is necessary for fattening cattle?
24. Describe the method of getting fattening cattle on feed.
25. Discuss the frequency and order of feeding for fattening cattle.
26. Summarize the chief facts concerning the use of pigs to follow fattening cattle.
27. About how much do cattle shrink that are 36 hours or less in transit to market? How can shrinkage be reduced to a minimum?
28. Discuss the production of veal.

CHAPTER XXX

GENERAL PROBLEMS IN SHEEP PRODUCTION

I. Factors Affecting Sheep Husbandry

1260. Sheep production in the United States.—More than two-thirds the total number of sheep in this country are in the western states, where most of them are kept under range conditions in bands of from 1,000 to 3,000 head. Differing widely from this type of sheep production, sheep raising in the rest of the country is usually combined with other types of farming and commonly there are only 25 to 100 breeding ewes in each flock.

Usually, sheep raising is not the main source of income on farms where there are farm flocks, but because of its particular advantages, it is combined with other enterprises. Sheep do not need expensive buildings or equipment, the foundation animals are relatively cheap, and the flock can be increased rapidly. Sheep require but little labor during the busy summer, and the cares of lambing time can be over before spring work begins. The wool and the market lambs provide two sources of income each year, and returns come quickly, for lambs may be marketed 9 months after the ewes are bred. While excelled by pigs in economy of meat production, lambs require slightly less feed per pound of gain in weight than do fattening calves.

Sheep Keep Lanes and Fence Rows Clean

On many farms where most of the income is derived from other sources, a flock of sheep brings additional returns, since they consume much forage that would otherwise be wasted.

Sheep are especially adapted to grazing on rough and hilly land, and therefore farm flocks are most common where much of the land is unsuited for tillage. Sheep are without equals as weed destroyers, for they will eat nearly all of the common weeds, and they grind their

feed so finely that they destroy most weed seeds. A moderate-sized farm flock can often secure no small part of its feed by cleaning up the lanes, stubble fields, and fence rows. Although such waste should be fully utilized, one should not rely too largely on it. To secure good results from sheep, they must have sufficient feed at all times.

The effectiveness of sheep in cleaning out weeds is shown by the fact that some sugar cane growers in Louisiana use sheep to control Johnson grass in the cane fields.[1] Other farmers graze sheep in tung orchards to clean out weeds and brush. Not only is much labor thus saved, but also the sheep pay in wool and mutton for doing the work.

For success with sheep, it is even more essential than with other classes of stock that they be given careful attention, especially during the periods of breeding, lambing, and weaning. However, the principles of feeding and management are relatively simple. In some districts the dog nuisance is a serious obstacle in raising sheep, but fortunately several states have effective dog laws which protect the sheepman. Also, the flock may be safeguarded by means of fences, corrals, and trained dogs.

Usually, there should be at least 40 ewes in a farm flock, so as to reduce the expense per head for shelter, equipment, and labor, and the cost of keeping a good ram. Often the flock can advantageously be much larger than this, but if a farm is too heavily stocked with sheep, the troubles from stomach worms and other parasites are greatly increased. For this reason, but few farm flocks contain more than 200 ewes.

1261. Types of sheep.—The original fine-wool or Merino sheep were developed primarily for the production of wool and have bodies which, like those of dairy cows, are angular in form. At the other extreme are the mutton sheep, comprising the medium- and long-wooled breeds, which were developed primarily for the production of meat, with wool secondary. In shape of body these breeds resemble the beef breeds of cattle, being blocky and compact. The Rambouillets and the Delaine-Merinos were developed from the original Spanish Merinos to secure a fine-wool sheep that would furnish more mutton.

On the western ranges sheep carrying some mutton blood are desired, so that the lambs will yield good carcasses. However, unless the range ewes have considerable fine-wool blood, they will lose both their hardiness and their herding instinct and will scatter on the range, so that many will be lost or fall prey to wild animals. A system of cross breeding is therefore followed in range flocks, or such breeds as the Corriedale and the Columbia are used, which have been developed by crossing fine-wool and mutton breeds.

It is outside the field of this volume to discuss the characteristics or merits of the different breeds of sheep. Tests have been conducted at several experiment stations to compare various breeds or to determine the relative value of rams of different breeds for crossing on native or scrub ewes. These studies show that lambs of the fine-wool type are slower in maturing than lambs of the mutton breeds and therefore usually make smaller daily gains and require somewhat more feed for each pound of gain.

Among the mutton breeds, there may be quite as much difference in gaining capacity and economy of gain between various strains of one breed as there is between the different breeds. In deciding upon the breed to raise, one should therefore select the breed that seems best adapted to his own local conditions and to the requirements of his particular market.

1262. Building up the farm flock.—Often the most economical way for a farmer to establish a flock of sheep is to buy young, thrifty western range ewes of good conformation. These are commonly less infected with internal parasites than are native eastern ewes. By the continued use of good purebred rams of the same mutton breed, a flock of excellent mutton type and conformation may soon be built up that can scarcely be distin-

guished from purebreds. Even the lambs of the first cross will show pronounced improvement in mutton characteristics.

If native ewes are purchased locally to start the flock, it is important that they be vigorous, thrifty, free from disease, and of as uniform breeding as possible. In certain sections, native fine-wool ewes can be purchased more cheaply than ewes of mutton type. Provided they are thrifty, they make desirable foundation stock for building up a farm flock by the use of purebred mutton rams.

If one already has a flock of ewes, but they are of rather poor quality, he can make rapid improvement and thereby greatly increase the income from his sheep by using only a good purebred ram. For example, in North Carolina experiments half-blood ewes from purebred Hampshire or Shropshire rams and unimproved dams averaged 108 lbs. in weight, sheared 5.0 lbs. of wool per head, and produced lambs of good quality that averaged 73 lbs. in weight at 5 months of age.[2] Native ewes weighed only 70 lbs. and sheared only 3.1 lbs. of wool of shorter staple. Their lambs, sired by a scrub native ram, averaged only 51 lbs. at 5 months of age and yielded low-grade carcasses. Similar striking examples of the rapid improvement through the use of good purebred rams have been reported by the Kentucky, Mississippi, Nevada, Oklahoma, South Carolina and West Virginia Stations.[3]

1263. Lambs preferred to older sheep.—The tender, juicy, well-flavored meat from lambs is in far greater demand than mutton from older sheep. Hence, fat lambs sell for a much higher price per hundredweight than do older animals. Also, lambs make much cheaper gains than do older sheep. Thus, in a Kansas trial the feed cost of 100 lbs. gain was 56 per cent more for yearlings than for lambs, and in a Texas test 35 per cent greater.[4] For these reasons, practically all the lambs that are raised for meat are marketed before they are a year old.

Most stockmen who fatten western feeder sheep for the market prefer lambs. Though they cost more per hundredweight as feeders than do older animals, they sell for so much more when fat that there is usually a greater margin between cost and selling price per hundredweight, and hence a greater profit in fattening them. Some men make a practice of fattening old ewes, which can often be obtained at low prices. Such animals must be carefully selected and require expert care and good feed.[5] In the West they are often fed largely on beet pulp, as this is especially suited to those with "broken mouths," or poor and missing teeth.

II. Nutrient Requirements of Sheep

1264. Importance of plenty of good roughage for sheep.—For success with sheep, it is essential that they have an abundance of first class roughage. This means plenty of good pasture throughout the growing season and a liberal supply of good roughage in winter.

High-quality roughage is even more important for sheep than it is for dairy cattle or beef cattle. For example, it has been shown in the preceding chapter that if beef cows are in good condition in the fall, they generally have a satisfactory calf crop when wintered on straw as the only roughage, with supplements to furnish sufficient protein and minerals. However, Indiana experiments show that such a ration is very inadequate for pregnant ewes.[6]

In these experiments the results were decidedly unsatisfactory when ewes were wintered on oat straw, grain, salt, and a rather small amount of corn silage, even though soybean oil meal, ground limestone, and bone meal were added to furnish plenty of protein, calcium, and phosphorus. The lambs tended to be weak at birth and the ewes did not supply enough milk for good growth of their offspring. On the other hand, the results were excellent when high-quality alfalfa hay was fed.

These and later Indiana studies showed that the beneficial effects of the good legume hay were due in part to unknown vitamins or other factors, in addi-

tion to protein, calcium, and the common vitamins. The results were fair on corn silage as the only roughage, with a proper amount of protein supplement and a simple mineral mixture. However, alfalfa hay or dehydrated alfalfa meal contributed something additional to the well-being of the ewes and their lambs. Lambs from ewes receiving some alfalfa had a lower rate of mortality.

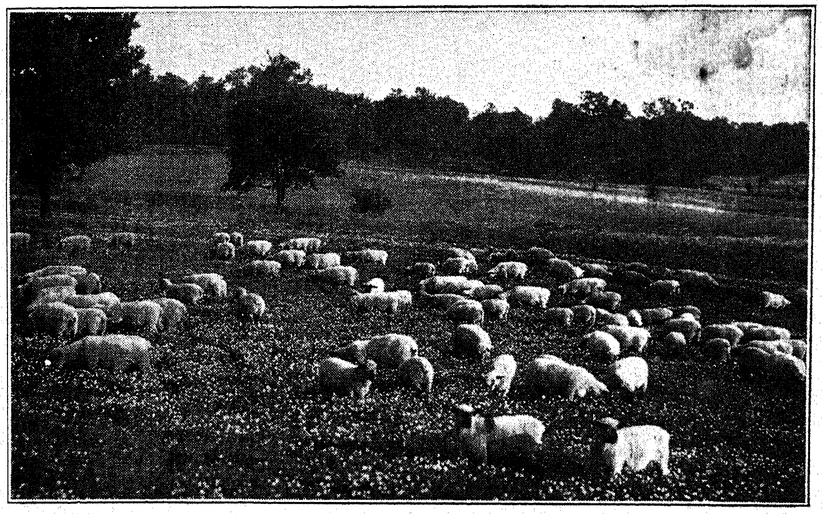
These and other experiments show that whenever possible, ewes should be supplied with plenty of well-cured legume hay in winter, or with good mixed hay that has a considerable proportion of legumes. Silage is also very satisfactory, especially as part of the roughage. (1307)

To be suitable for sheep feeding, grass hay must be cut early and be well cured. It has been shown previously that in Ohio experiments timothy hay cut in early bloom was satisfactory for pregnant ewes, when properly supplemented. (566) On the other hand, the results were very poor with late-cut timothy hay as the only roughage.

High-quality roughage, especially legume hay or silage, is also necessary for the best results in fattening lambs, as is emphasized in the following chapter. (1331)

1265. Nutrient requirements; feeding standards.—Detailed information concerning the amounts of nutrients required by various classes of sheep is given in the feeding standards presented in Appendix Table III. These state the amounts of dry matter, digestible protein, and total digestible nutrients to be fed per head daily. Net-energy recommendations are also given, so that rations can be computed on the net-energy basis, if desired. The standards also state the amounts of calcium, phosphorus, and carotene advised per head daily for the various classes of sheep.

These standards are based on studies by the author of the results of the experiments that have been conducted to find the nutrient requirements of sheep, especially the recent studies on the protein requirements of ewes and of fattening lambs, which are reviewed in the following articles. Full consideration has also been given to the report of a special committee of the National Research Council, entitled "Recommended Nutri-

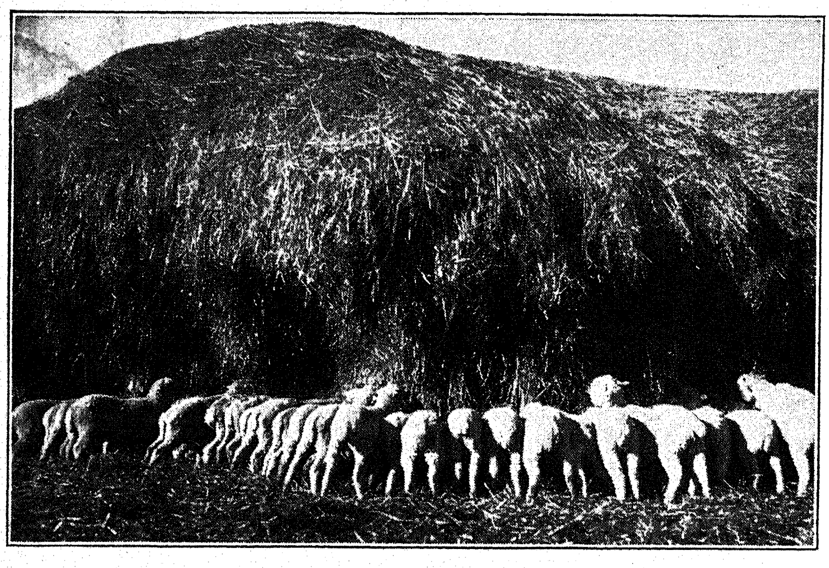


GOOD ROUGHAGE IS ESSENTIAL FOR SHEEP

For success with sheep, it is essential that they have plenty of first-class pasture throughout the growing season and a liberal supply of good roughage in winter.

ent Allowances for Sheep,"[7] and to the modifications of these allowances presented by Kammlade.[8]

To serve as guides in selecting well-balanced, efficient rations, several example rations are given in Appendix Table VII for breeding ewes and for fattening lambs. These example rations show the approximate amounts of various feeds needed per head daily for the different classes of sheep. They also show when protein supplements are needed to balance the ration, and the amount of supplement that should be supplied.



STRAW IS UNSATISFACTORY AS THE ONLY ROUGHAGE

Straw is a very poor feed for sheep. However, when hay is scarce, a limited amount of straw can be fed along with legume hay or legume hay and silage.

1266. Amounts of protein for ewes.—Since wool fibers are composed almost entirely of protein, sheep need a somewhat greater proportion of protein in their rations than would be required if they were not making this protein product. However, extensive recent studies at the North Dakota Station and the Lethbridge Station in Alberta, Canada, show that if mature ewes come off good summer pasture, they can be wintered satisfactorily up to lambing time on considerably less protein than was formerly thought necessary.[9] Other information on the subject is furnished by recent Montana, Oklahoma and South Dakota trials.[10]

During the last 4 to 6 weeks of pregnancy, ewes need more protein than previously, because the growth of the fetus is then most rapid. After lambing, considerably more protein is required, in order to secure the good milk flow necessary for rapid growth of the lambs.

The experiments have shown that mature ewes in good condition in the fall will generally produce thrifty lambs when they are wintered, up to 4 to 6 weeks before lambing, on a ration that has only 7 per cent protein supplying only 0.10 lb. digestible protein a day. During the last weeks of pregnancy, at least 10 to 11 per cent of protein is needed in the ration.

Though thrifty lambs have been produced on these very low levels of protein, the wool production of the ewes is reduced. Somewhat more liberal amounts of protein are therefore recommended in the revised feeding standards given in Appendix Table III. Ewes that

are still growing need more protein than those which are mature.

The low levels of protein mentioned are successful only when the ewes have a ration that provides ample energy and is complete otherwise, having roughage of satisfactory quality. Also, it is essential that the ewes be well fed after lambing, or they may not yield enough milk to raise their lambs, especially if they have twins. After lambing, the ration should have not less than 11 per cent total protein, and should furnish at least 0.25 lb. digestible protein per head daily.

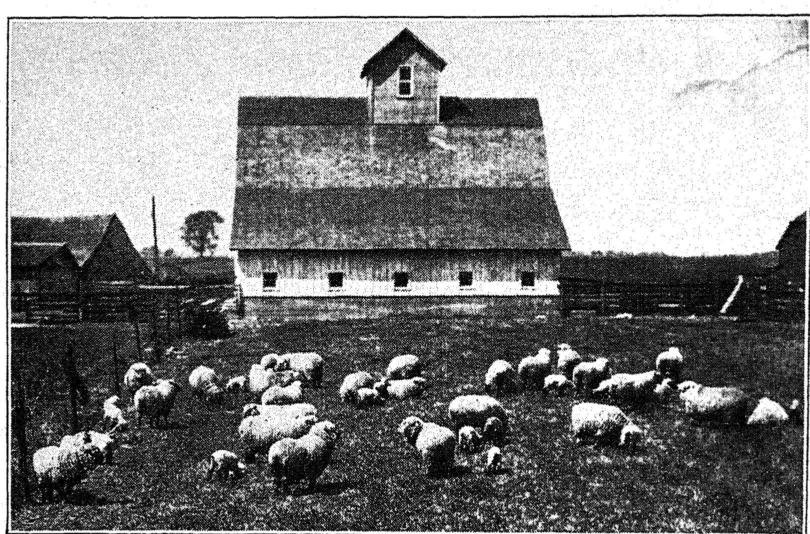
The disastrous effects of a ration too low in protein are shown by an Oklahoma trial.[11] When ewes were wintered on prairie hay alone or prairie hay plus starch to provide plenty of energy, 75 per cent or more of the lambs were dead at birth or died shortly afterwards. On the other hand, the results were satisfactory when a protein supplement was fed.

Rations for breeding ewes are discussed further in Chapter XXXI. (1306–1308)

1267. Amount of protein for fattening lambs.—The protein requirements of fattening lambs have been studied in a considerable number of experiments. Some of these experiments have been carried on to find whether or not it pays to add a protein supplement to various rations. In other trials the effect has been determined of adding various amounts of a protein supplement to typical rations for fattening lambs.

The most extensive of such experiments are those at the New York (Cornell) Station.[12] These New York studies have included both practical feeding experiments and also metabolism experiments in which the actual storage of protein in the body has been determined. In these experiments, lambs which usually weighed 50 lbs. or more at the start have been full-fed rations containing various percentages of protein until they were well fattened.

These experiments have shown that lambs of this age will make rapid gains and reach good finish on rations having about 10.3 per cent of total protein, on the air-dry basis. The nutritive ratios of such rations ranged between 1 : 7 and 1 : 8. Increasing the percentage of protein to 11.8 per cent produced slightly



EWES NURSING LAMBS NEED AMPLE PROTEIN

Ewes nursing lambs require a somewhat larger proportion of protein in their rations than do dairy cows.

more rapid gains, but the lambs were not so fat as those fed rations having 10 to 11 per cent protein.

Much lower amounts of digestible protein were advised by Mitchell for growing and fattening lambs.[13] However, in several of the New York experiments, lambs fed such low amounts of protein, in a ration otherwise adequate, have failed to make satisfactory gains.[14]

1268. Quality of protein.—It has been emphasized in Chapter V that at least when sheep are fed roughage of good quality, it is unnecessary to consider the *quality* or kind of protein supplied by ordinary feeds. (127) In New York metabolism experiments, growing lambs utilized the protein of corn gluten meal just as efficiently as the protein of soybean oil meal or dried skimmilk. This was true even when corn gluten meal furnished nearly all the protein in an experimental ration having very little natural roughage. For swine or poultry, the protein of corn gluten meal would have been decidedly inferior.

In practical feeding experiments with fattening lambs also conducted at the New York (Cornell) Station, corn gluten meal was about equal to soybean oil meal or linseed meal as the protein supplement to a ration of corn grain, corn silage, a very small amount of mixed hay, and ground limestone.[15] These results differ from similar New York experiments with fattening cattle, which have been discussed previously. (715) For fattening cattle, corn gluten meal was a decidedly less efficient supplement than linseed meal, soybean oil meal, or ground soybeans. This difference between the results with fattening lambs and with fattening cattle may be due to the fact that cattle full-fed on grain eat a much smaller proportion of roughage and a much larger proportion of grain than do fattening lambs.

It has been shown previously that for fattening cattle certain combinations of protein supplements are usually superior to such single supplements as cottonseed meal or corn gluten meal. (1167) However, in experiments with fattening lambs there has been little or no advantage in using such combinations of protein supplements as the following:[16] (1) Equal parts of linseed meal and cottonseed meal; (2) equal parts of gluten meal and either linseed meal or cottonseed meal; or (3) a triple combination of equal parts of the 3 supplements.

In a Colorado trial Purdue Supplement A, the use of which for beef cattle has been previously discussed, was not superior to soybean oil meal as the supplement to corn silage for fattening lambs.[17] (1178)

Although the quality of protein in protein supplements is not ordinarily important when sheep are fed good roughage, it may make a difference when the roughage is poor. Peas, which are low in methionine, the essential sulfur-containing amino acid, were not so good as linseed meal or alfalfa hay, fed as the supplement to poor grass hay for ewes in a Canadian trial.[18] In North Dakota studies with ewes the utilization of protein was improved when methionine was added to certain experimental rations in which peas supplied most of the protein.[19] It has been shown in Chapter XXII that, even with good roughage, raw beans are not satisfactory as the only protein supplement for fattening lambs. (844)

Wool is very rich in cystine, one of the two sulfur-containing amino acids, but there is apparently no lack of cystine in ordinary rations that are otherwise satisfactory for sheep.[20] If sheep are fed a ration unusually low in cystine, there may possibly be a benefit from using a protein supplement high in this amino acid or in methionine, the other sulfur-containing amino acid. Thus, in an Australian test with Merino sheep, whose wool production is high, blood meal (a feed rich in cystine) gave excellent results as a supplement to pasture grass that was exceedingly low in cystine.[21]

1269. Urea as a protein substitute.—The conditions necessary to enable ruminants to utilize urea as a substitute for part of the protein in the ration have been discussed in some detail in Chapter V. (129) For some unknown reason,

urea is generally a less satisfactory protein substitute for sheep than for dairy cows or for beef cattle.

A low-protein ration for sheep will be improved somewhat by the addition of urea. However, the results will generally be still better when the ration is balanced with one of the usual protein supplements.

Several metabolism experiments have proved that under proper conditions sheep can use urea as a partial substitute for protein.[22] But in most such studies urea has not equalled a protein supplement.

Sheep need more sulfur than do cattle, because of the richness of wool in cystine. Probably for this reason, if urea replaces a considerable part of the protein, the utilization may be improved by adding a sulfate, or even free sulfur, or else by adding methionine, the essential sulfur-containing amino acid. (**176**) However, even then the nitrogen in urea is apt to be less efficient than that in real protein.

Several experiments have been carried on to study the use of urea as a partial substitute for protein supplements in rations for fattening lambs.[23] When urea has replaced as much as one-half of the protein supplement commonly fed, the gains have been appreciably lower in most of the trials. Even when less urea has been used, there has been a tendency for the ration to be less satisfactory than with one of the ordinary protein supplements.

Urea has produced somewhat better results when used as a partial protein substitute for wintering breeding ewes.[24] However, in the majority of the experiments, the urea-containing rations have not been fully equal to rations balanced with such a protein supplement as soybean oil meal or cottonseed meal.

1270. Adding a protein supplement to legume hay and grain.—Many experiments have been conducted to find whether or not it pays to add a protein supplement to a ration of grain and legume hay for fattening lambs. These trials have shown that when lambs are fed a liberal amount of good legume hay with corn or other grain, there is usually enough protein to produce very satisfactory gains, without the addition of any protein supplement.

This is because full-fed fattening lambs continue to eat considerable hay, even during the latter part of the fattening period. The proportion of hay in the ration is thus considerably larger than in the case of fattening cattle full-fed on grain.

Adding a small amount of protein supplement (0.10 to 0.15 lb. per head daily) to such a ration as alfalfa hay and corn for fattening lambs will commonly make a slight increase in the rate of gain, unless the hay is of especially good quality and high protein content. However, the increase will not average more than 0.05 lb. per head daily. The supplement usually stimulates the appetite of the lambs slightly, so that they eat more total concentrates (grain plus supplement) than they would if fed only grain and hay.

This stimulating effect of the protein supplement may be due to some other factor than the additional protein the supplement supplies. This is indicated by the fact that a ration of corn grain and good alfalfa hay, both full-fed, will usually have fully 12 per cent protein. This is more protein than lambs seem to need for maximum gains. (**1267**)

Though the addition of a protein supplement to a ration of corn and good legume hay increases the rate of gain a trifle, nearly as much feed is required per 100 lbs. gain as on the unsupplemented ration. It is therefore doubtful if it will ordinarily pay to add a supplement to such a ration, if the hay is of good quality and an abundance is fed.

If one desires to secure maximum gains, so as to have the lambs ready for market as soon as possible, it may be advisable to feed a supplement. Otherwise, it is usually best to omit the supplement and to continue the lambs on feed the few days longer that will be needed to reach the desired finish. During the last few weeks of the fattening period, when lambs full-fed on corn tend to eat less hay than previously, there may be

more advantage in adding a small amount of supplement to the ration.

The effect of adding a supplement to a ration of corn and good alfalfa hay, both full-fed to fattening lambs, is shown by the results of 57 experiments in which either linseed meal or cottonseed meal has been added to this ration.[25] The average daily gain has been increased only 0.05 lb. by feeding the supplement. Not considering this slight difference in rate of gain, each 100 lbs. of protein supplement has saved an average of 94 lbs. corn and 88 lbs. hay in these many trials.

At the usual prices for the protein supplements in comparison with the prices of corn and hay, adding the supplement has increased the feed cost per 100 lbs. of gain in weight. Therefore, the addition of the supplement has generally not been profitable.

If barley, wheat, oats, or grain sorghum is fed with legume hay, the addition of a protein supplement does not cause even as much increase in rate of gain as adding a supplement to corn and legume hay.[26] This is because these grains generally are richer than corn in protein.

Red clover hay usually has somewhat less protein than does alfalfa hay. Nevertheless, adding a protein supplement to a ration of only shelled corn and good clover hay for fattening lambs increased the daily gain only 0.01 lb. in 9 trials and did not decrease the amount of feed required per 100 lbs. gain.[27]

1271. Adding a supplement when non-legume roughage is fed.—When fattening lambs are fed grain and only non-legume roughage, such as corn silage or grass hay, satisfactory gains cannot be secured unless enough protein supplement is fed to balance the ration. (698) When the roughage is mixed legume-and-grass hay or a combination of legume hay and corn or sorghum silage, a supplement is also usually needed, though a smaller amount is required.

If fattening lambs are given all the corn silage or sorghum silage they will eat and are also full-fed legume hay and grain, they will naturally eat somewhat less hay than when hay is the only roughage. Nevertheless, they will generally eat 0.75 to 1.00 lb. of hay per head daily, if it is of good quality. This will provide enough protein to make good gains, but it will usually pay to add about 0.15 lb. of a protein supplement to the ration. Such an addition will aid in keeping the lambs on feed, will increase the gains slightly, and will produce a better finish. Consequently, it will increase the selling price. When protein supplements are unusually high in price compared with grain, it may be most profitable to omit the supplement.

In 12 experiments with fattening lambs, the addition of 0.16 lb. per head daily of linseed meal or cottonseed meal to a ration of alfalfa hay, corn silage, and corn grain increased the daily gain 0.05 lb. on the average, raised the average selling price by 23 cents per hundredweight, and increased the average net return per lamb by 37 cents.[28] Not taking into consideration the more rapid gains or the increased selling price, each 100 lbs. of supplement saved 132 lbs. corn, plus 114 lbs. hay and 100 lbs. silage. Similar results have been secured in trials where a supplement has been added to a ration of corn, clover hay, and corn silage,[29] or to a ration of other grains fed with silage and legume hay.[30]

Whether or not it will pay to add a protein supplement to a ration of alfalfa hay, wet or dried beet pulp, and grain, will depend primarily on the amount of hay the lambs eat and on its quality.[31]

1272. Total digestible nutrients; net energy.—The amounts of total digestible nutrients and of net energy advised per head daily for ewes and for fattening lambs are stated in Appendix Table III. An abundance of good roughage alone will usually supply sufficient total digestible nutrients or net energy for breeding ewes in winter up to about a month or six weeks before lambing. A small amount of grain or other concentrates should then be fed, on account of the rapid growth of the unborn lambs at that time. Another reason why concentrates are then needed is that the capacity of the ewe to consume rough-

age is considerably reduced, because of the space in the abdomen that is occupied by the lamb or lambs and the fetal membranes.

It is emphasized in the next chapter that if ewes are severely underfed before lambing they frequently have weak lambs, and are unable to raise them because of a poor flow of milk. (**1305**) Underfed ewes are also more apt to have pregnancy disease. (**1314**)

Ewes that are suckling lambs need a liberal supply of total digestible nutrients. Therefore, ewes lambing before they go to pasture need a sufficient amount of concentrates, in addition to good roughage, to keep up a good milk yield. If they are on suitable pasture, they need be fed no concentrates.

In order to fatten lambs rapidly, so that they will reach the desired degree of fatness before they become too large, they must receive a liberal amount of grain or other concentrates, in addition to plenty of good roughage. (**1331**) However, restricting the roughage and feeding an undue amount of grain will lead to less efficient use of feed and greatly increase the danger of overeating disease. (**1333**)

1273. Addition of fat to rations.—When the price of low-grade animal fat is low, compared with an equal amount of energy in grain, it may be economical to add a small percentage of such fat to rations. (**914**)

In a Texas trial the addition of 5 per cent of tallow or grease to a mixed ration increased the gain slightly and reduced the feed cost per 100 lbs. gain, with the fat costing 1.8 times as much per pound as sorghum grain.[32] Adding 10 per cent or more of the fat to the ration decreased the gains.

In a New York trial, adding 6 per cent of yellow grease or tallow did not appreciably increase the rate of gain, and it slightly reduced the selling price of the lambs.[33] With the fat costing 2.4 times as much per pound as shelled corn, the return per lamb above feed cost was higher without the added fat.

Replacing part of the corn in a typical lamb fattening ration with 4 per cent of animal fat did not affect the digestibility of the ration in an Iowa trial.[34] A greater percentage decreased the digestibility. Hydrogenated animal fat, which had a very high melting point, was utilized less completely than was tallow or corn oil.

1274. Mineral requirements.—Except in the areas where there is a deficiency of one or more of the trace minerals, the only minerals that need consideration in feeding sheep under usual conditions are salt, calcium, and phosphorus. Calcium, phosphorus, and trace minerals are discussed in the articles which follow.

In districts where there is trouble from goiter in new-born lambs, the ewes should receive iodized salt during at least the latter half of pregnancy. (**170**) It is doubtful whether there is any benefit from using iodized salt in place of ordinary salt for fattening lambs, except possibly in areas where there is a decided deficiency of iodine. (**171**) Adding too much iodine to a ration may produce serious injury.[35]

There is no need to add complex mineral supplements to the usual rations of sheep.[36] (**187**)

1275. Salt.—Sheep show a special fondness for salt and consume considerably more salt per 100 lbs. live weight than do cattle. Under any ordinary conditions, they should be furnished salt regularly. When sheep are accustomed to salt, it is the best plan to let them have access to it in suitable boxes or other containers, so they can take what they wish. Ewes will usually eat one-fourth to one-half ounce of salt a day, and fattening lambs one-fifth to one-fourth of an ounce.[37]

In Iowa trials better results were secured from ewes fed one-fourth to one-half ounce of salt per head daily or allowed free access to salt, than when larger amounts were mixed with the feed or when no salt was supplied.[38]

Fattening lambs that were supplied with salt gained an average of 0.04 lb. more per head daily in 3 Kansas trials, than did others having no salt.[39] The

feed cost per 100 lbs. gain was considerably less with salt than without it.

Feeder lambs shipped from the western range have usually had no salt when in transit. Therefore, in starting them on feed they should gradually be accustomed to salt.

On the western ranges allowances of salt equivalent to one-fourth to one-half ounce per ewe daily (not counting the lambs) are considered reasonable.[40] Often the sheep are salted at intervals of 3 to 7 days, instead of daily. In the alkali districts, sometimes range sheep are not salted, but merely allowed to eat alkali. This is safe, if the alkali contains 85 per cent salt.[41]

1276. Self-feeding a mixture of protein supplement and salt.—Information has been given in previous chapters about self-feeding a mixture of protein supplement and salt to range livestock, instead of feeding the protein supplement daily. (**142, 1170**) This labor-saving method is used not only for beef cattle, but also for sheep. The precautions necessary in self-feeding such a mixture have been stated previously.

In California studies a mixture of 25 per cent salt and 75 per cent of protein supplement was successfully used for pregnant and lactating range ewes.[42] The high salt consumption had no injurious effects.

1277. Calcium and phosphorus.—Whether or not there will be any advantage in adding a calcium or a phosphorus supplement to rations for breeding sheep or growing and fattening lambs will depend entirely on the amounts of these minerals supplied by the feeds they receive. Whenever there is apt to be a deficiency of either of these mineral nutrients, a suitable mineral supplement should be provided, as advised in Chapter VI. (**149–150, 186**) The feeding standards in Appendix Table III state the amounts of calcium and phosphorus advised per head daily for various classes of sheep.

1278. Calcium.—When at least one-third of the roughage (on the dry basis) for sheep and lambs is legume hay or other legume forage, there will be abundant calcium. Experiments with breeding ewes[43] and with fattening lambs[44] have shown that under such conditions there is no benefit from adding ground limestone or some other calcium supplement to the ration.

There is generally no lack of calcium when sheep are on good pasture. However, if the soil is unusually low in the mineral, it is wise to provide a mineral mixture supplying calcium. Wyoming studies indicate that the occurrence of "broken mouths" in ewes on the Red Desert ranges of that state is due, at least in part, to a lack of calcium.[45]

When no legume hay or other legume forage is fed to sheep, there may be a decided lack of calcium in winter rations, especially where the forage is grown on soil very low in calcium. Calcium should then be supplied by adding 0.25 to 0.40 ounce per head daily of ground limestone or other calcium supplement to the ration, or else by letting the sheep have access to a suitable mineral mixture.

Experiments at the Kansas, Nebraska, and Texas Stations show that a lack of calcium is one cause of the poor results often secured when lambs are fattened on rations without legume forage.[46] Lambs fed sorghum silage or fodder as the only roughage, with corn or sorghum grain and cottonseed meal, made decidedly slower and more expensive gains than others that had alfalfa hay for roughage. However, when 0.25 to 0.40 ounce per head daily of ground limestone or pulverized oyster shell was added, much better results were secured. The results were similar in Minnesota and Ohio trials, in which prairie hay or timothy hay was the only roughage for fattening lambs.[47]

Likewise, in Ohio trials satisfactory results were secured with breeding ewes fed only timothy hay and corn silage for roughage, if the hay was cut in early bloom and if 0.8 ounce of ground limestone per head daily and a sufficient amount of protein supplement were added to the ration. (**566**)

In certain other trials there has been

an advantage from adding a calcium supplement to a ration containing no legume hay, while in others no advantage has resulted.[48] This difference in results is probably due to the fact that non-legume roughage varies widely in amount of calcium, depending on the calcium content of the soil.

If non-legume roughage is grown on soil fairly well supplied with calcium, it will take relatively little legume hay to provide enough additional calcium for fattening lambs. For example, in Indiana trials there was no benefit from adding a calcium supplement when fattening lambs were fed corn silage, corn grain, and cottonseed meal, with a full feed of good clover hay only every fifth day.[49]

As has been pointed out in the case of beef cattle, adding a calcium supplement to a ration that is marginal in phosphorus content may be definitely injurious.[50] (**1171**)

1279. Phosphorus.—Extensive experiments have been conducted by the Idaho Station to determine the phosphorus requirements of ewes [51] and of fattening lambs.[52] These investigations show that a phosphorus content of only 0.16 to 0.19 per cent in the entire ration (air-dry basis) is adequate for ewes during pregnancy. When they are suckling their lambs, their rations should have 0.23 per cent phosphorus.

The Idaho studies and also Oklahoma experiments show that for fattening or growing lambs, about 2 grams of phosphorus daily per 100 lbs. liveweight is sufficient.[53] Such rations will have approximately 0.17 per cent phosphorus on the air-dry basis.

When low-phosphorus rations were fed to pregnant ewes, abortion or weak lambs resulted. Phosphorus-deficient rations for fattening lambs resulted in low gains, poor utilization of feed, and depraved appetite.

There will commonly be no lack of phosphorus for ewes or fattening lambs when they are fed grain and plenty of good hay or other roughage, unless the forage is grown on land very deficient in phosphorus.[54] This is because the grains usually have 0.27 per cent or more of phosphorus and good hay generally has at least 0.19 per cent. Corn silage, reduced to the air-dry basis, has even more phosphorus, but the content in sorghum silage seems to be somewhat lower. When ewes are wintered on only good hay or hay and silage until a few weeks before lambing, they will usually have enough phosphorus, unless the forage is unusually low in phosphorus.

When sheep are wintered chiefly on mature, weathered range forage, as in many districts of the West, there may be a decided deficiency of phosphorus.[55] Also, there may be a serious lack of phosphorus when feeds that are particularly low in phosphorus form a considerable part of the ration for ewes or fattening lambs. Such feeds are beet pulp and beet molasses.

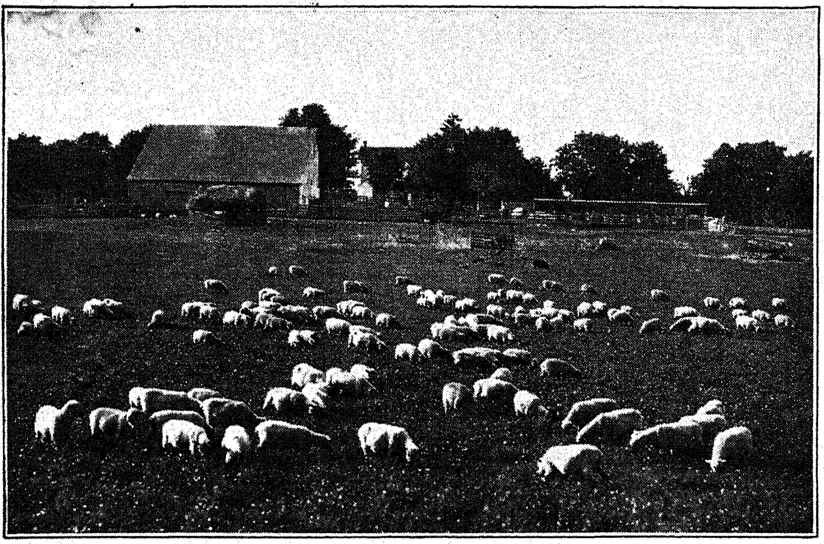
Whenever there is apt to be a lack of phosphorus, a low-fluorine phosphorus supplement should be supplied, as recommended in Chapter VI. (**158, 169**) Sheep on pasture seem to be less apt to show a lack of phosphorus than do cattle on the same pasture. This may be because sheep have a very selective habit of grazing.

When there is already an ample supply of calcium and phosphorus in the ration, forcing sheep to consume a calcium or phosphorus supplement may even be detrimental. For example, in the case of breeding ewes, too liberal a supply of these minerals may even perhaps cause more cases of difficult lambing, because of an increase in the size of the skeleton of the lambs.

1280. Trace minerals.—In an area where there is a deficiency of a trace mineral, it is essential that the lack be corrected, as has been emphasized in Chapter V. (**173, 175**) In other areas there is no advantage in using trace-mineralized salt instead of ordinary salt, or in supplying a mineral mixture that furnishes cobalt, copper, or iron.[56]

The striking benefits produced by a cobalt supplement in deficient areas are well shown by Wisconsin studies.[57] In certain sections of northern Wisconsin sheepmen were having disastrous results

in their flocks. For example, in one flock of 1,300 ewes and lambs, all but 200 died during the year. When a mineral mixture containing cobalt was supplied the sheep in these flocks, the troubles were entirely prevented. Later studies showed that when a mineral mixture containing both cobalt and bone meal was supplied for sheep on pasture, they were protected to some degree from injury from stomach worms. New York experiments have also shown the disastrous results from feeding lambs a cobalt-deficient ration.[58]



ABUNDANT SUPPLY OF VITAMINS ON GOOD PASTURE

Sheep on such pasture have an abundant supply of vitamins. Legume or mixed legume-and-grass pasture is also rich in protein and calcium.

Although the area around Cornell University, New York, is not decidedly deficient in cobalt, the content is apparently marginal. In 3 experiments fattening lambs gained appreciably more when cobalt was added to the ration, unless at least 0.1 lb. linseed meal was fed per head daily. This amount of linseed meal evidently furnished sufficient cobalt, as it is higher in the mineral than most other feeds.[59]

1281. Vitamin requirements—If sheep have plenty of good roughage, including pasture during the growing season, all of their vitamin needs are usually met. Pasture that is at all suitable for sheep is high in vitamin A value (carotene content). In the fall, sheep that have been on good pasture during summer will consequently have a considerable store of vitamin A in their bodies. (**192**) If ewes or lambs are then fed hay of reasonably good quality or other satisfactory roughage, they will have plenty of vitamin A.

It has been emphasized previously in this chapter that it is always advisable to provide pregnant ewes with high-quality roughage in winter. (**1264**) Experiments have shown, however, that if ewes have been on first-rate pasture during the growing season, they may produce normal lambs when fed roughage low in carotene during most of the winter.[60] It is not safe to continue such a ration too long, for the ewes may become depleted in vitamin A. They will then suffer from the deficiency, and the lambs may be born so weak that they soon die, or the milk of the ewes may have so little vitamin A that the lambs are seriously affected.

Under any usual conditions in the United States there is apparently no need of feeding a vitamin D supplement to sheep.[61] The fact that they are generally outdoors and exposed to sunlight much of the time, even in winter, protects them against any deficiency of vitamin D. Also, field-cured hay or fodder supplies the vitamin. However, as stated in Chapter VII, rickets sometimes occurs in New Zealand in lambs on pasture, for some unknown reason.[62] (201) This can be prevented by a vitamin D supplement.

The B-complex vitamins are synthesized through the bacterial action that normally occurs in the rumen of sheep. Thrifty sheep that are digesting their feed properly therefore have no lack of these vitamins.[63] If sheep are very debilitated because of infection with internal parasites, the administration of yeast, before they are treated to remove the parasites, may be beneficial in order to restore their appetite and build them up. (957)

In a Wisconsin experiment there was no advantage in adding a vitamin B_{12} supplement to the ration of ewes nursing lambs, or to the creep feed given the lambs.[64]

It has been found in experiments where new-born lambs were fed synthetic milk, lacking B-complex vitamins, that they need a supply in their food, before the rumen is developed.[65] Fortunately, ample amounts are provided by their mothers' milk.

The ordinary rations fed sheep supply ample vitamin E for successful reproduction. (223) It is shown in the next chapter, however, that the stiff-lamb disease can be prevented by feeding vitamin E supplements. (1315)

It has been mentioned previously in this chapter that the poor results produced by feeding chiefly low-grade roughage, such as straw, to pregnant ewes, may be due in part to the lack of unknown vitamins which are supplied by high-quality roughage. (1263)

1282. Water.—Plenty of fresh water should always be furnished sheep, under all ordinary circumstances. Ewes on dry feed in winter may drink as much as 1 gallon per head daily before lambing and 1.5 gallons or more when nursing lambs. Lambs that are being fattened on dry feed will drink 1.2 to 2 quarts or more of water a day.[66]

When sheep are fed succulent feeds, such as silage or roots, they drink correspondingly less water. In districts with very heavy dews, sheep on pasture may get along without other water, and likewise when they are fed large quantities of roots in winter. More water is needed in warm weather than when it is cooler, and fattening lambs drink more as their grain allowance increases.

Because of the danger of infection with internal parasites, drinking from stagnant pools must be avoided. It is not necessary to warm water for sheep in winter. In some regions sheep even have to eat snow during much of the winter for their water supply, and apparently are not injured.

1283. Antibiotic feed supplements.—The results of the experiments conducted to determine the effects of adding either aureomycin or terramycin to fattening lamb rations have varied.[67, 68] (966) A more favorable response has usually been secured under commercial feedlot conditions than with carefully controlled experimental conditions because of the difference in disease levels present. When needed an antibiotic feed supplement should be fed at a level of 10 milligrams per pound of total ration. Carcass quality is not affected by such an addition.

Under some conditions, the addition of antibiotics to the ration has resulted in some reduction of enterotoxemia or "overeating disease," although recent New Mexico results show no benefit.[69]

If an antibiotic produces a response in a given situation, the cost of the addition should be balanced against such factors as reduction in disease, increased gain, and improved feed efficiency, to determine its net effect.

Some experiments have been conducted to determine the effects on suckling lambs of adding an antibiotic supplement to the creep feed, or of implanting an antibiotic pellet in the head,

under the skin.[70] Here again, the results have differed decidedly. There have been no benefits in as many trials as there have been increases in rate of gain.

1284. Arsonic supplements; surfactants; tranquilizers.—Little information is yet available concerning the effect of arsonic supplements on lambs. In Illinois experiments with 3 different types of arsonic compounds, none proved consistently beneficial with either a typical lamb fattening ration or with a diet using wheat straw as roughage.[71] If such compounds are added to the feed care should be taken not to include toxic levels, especially if water consumption is limited.

In South Dakota trials the addition of a surfactant to a ration for fattening lambs did not increase the rate of gain.[72]

A new "chemobiotic" (tetra alkylammonium stearate or dynafac) has given variable results. Recent work reported by Washington showed no effect on weight gains, market grade, or price of commercial lambs receiving 1 gram per head daily of this compound in the feed. On the other hand, work by a commercial laboratory showed improved feed efficiency and increased daily gain compared with other lambs receiving antibiotics in the feed.

Lambs fed tranquilizers (reserpine or hydroxyzine) have shown inconsistent results. Purdue work showed no effect on daily gain or feed efficiency, while certain commercial work and Iowa experiments demonstrated a distinct response on both gain and feed efficiency. Since lambs vary greatly in their response to diets due to their origin, breeding, and environment, more research needs to be conducted on this subject before valid recommendations can be made.

1285. Hormones for lambs.—The effects of implanting pellets containing stilbestrol or other hormones under the skin in the heads of lambs have been studied in several recent experiments. The implantation of stilbestrol pellets has generally increased the rate of gain of fattening lambs and lowered the amounts of feed required per 100 lbs. gain.[73]

However, the quality of the carcasses has been lowered appreciably in most of the trials. Even more important, implanting stilbestrol has sometimes had very injurious effects on the lambs. It has caused prolapse of the uterus in ewe lambs, and in wethers has produced prolapse of the rectum and blockage of the urinary tract, resulting in "water belly." Some large lamb feeders have had severe death losses of fattening lambs, apparently caused by implanting stilbestrol pellets.

In addition, the stilbestrol may produce earlier closure of the break joint in lambs, so that the carcasses are classed as yearling, instead of lamb. This reduces the price appreciably.

More limited data are available concerning the effects of implanting pellets containing other hormones. A commercial product is being made that has a combination of two natural sex hormones —progesterone and estradiol. Favorable results were secured with such pellets in a Michigan trial and a Minnesota trial, but in a Virginia test 5 out of 8 lambs implanted with such pellets died from prolapse.[74] In another experiment the carcasses from the implanted lambs graded lower.[75]

Several experiments have been conducted to evaluate stilbestrol supplementation of fattening lamb rations, in a manner similar to fattening cattle. (1183) Adding 2 mgs. of stilbestrol per head daily in the feed of fattening lambs increased gains, and did not lower carcass quality or produce side effects in Iowa trials.[76] Increased levels of stilbestrol lowered the carcass quality.

On the other hand, in a Kansas trial even 2 milligrams of stilbestrol per head daily affected the quality of the carcasses.[77] In Minnesota experiments adding stilbestrol to the ration increased the gain in some cases, but not in others.[78] The results with fattening lambs thus apparently differ from those secured with fattening cattle and this compound is not widely used at present.

In a Tennessee experiment the addition of stilbestrol to the ration of lambs had no effect on digestibility, but it did increase the retention of protein, calcium, and phosphorus.[79]

III. Miscellaneous Problems in Sheep Husbandry

1286. Grinding or crushing grain.—There is no benefit from grinding or crushing most kinds of grain for sheep, except for old sheep with poor teeth, for young lambs up to 5 to 8 weeks of age, or perhaps when fattening lambs are being self-fed such a mixture as grain and chopped hay. It is wise to grind such hard seeds as hull-less barley or millet, and also screenings containing a considerable proportion of small weed seeds.

Also, recent Texas experiments with fattening lambs show that grinding appreciably increases the value of the grain of combine-type sorghums, which have smaller and harder seeds than other grain sorghums.[80]

If grain is processed for sheep, it should be ground coarsely or crushed, instead of being ground to a fine meal, for this is less palatable to them. Similarly, pea-size linseed cake or cottonseed cake is somewhat preferable to linseed meal or cottonseed meal for sheep feeding.

1287. Chopping or grinding hay, fodder, or stover.—Many experiments have been conducted to find whether or not it pays to chop or grind hay for sheep.[81] These tests have shown that when hay of good quality is fed in suitable racks or bunks and only as much is fed as will be cleaned up reasonably well, extra expense for chopping the hay is generally not warranted. There is still less reason for grinding hay, since sheep are apt to prefer long hay to that which is ground. If hay is stored in chopped form when it is put into the barn, it should not be chopped so fine that it is dusty. (407)

If the hay is rather stemmy and of poor quality, the sheep can be forced to eat more of the stems by chopping it. However, if one has plenty of hay, it is doubtful whether chopping is desirable even then. A better plan may be to feed an abundance of the hay, so the sheep can pick it over and eat only the more palatable and nutritious part. The refused part can be used for bedding or be fed to cattle being roughed through the winter or to idle horses.

When self-feeders are used for feeding grain to fattening lambs, often a mixture of cut or ground hay and ground grain is self-fed, instead of grain and hay separately, in order to lessen digestive disorders and reduce the death losses. (1335) Also, if one wishes to crowd hand-fed lambs on all the grain they will eat, digestive trouble may be lessened by mixing chopped hay with the grain.[82] A mixture of chopped hay and grain is sometimes fed in starting fattening lambs on feed.

If fattening lambs are fed hay (even good alfalfa hay) with great liberality, as is a common practice in the western states, there may be an appreciable saving through chopping or grinding it. In western experiments chopping alfalfa hay, not too fine, has increased its value 18 to 19 per cent,[83] and grinding the hay has made twice as large an increase in value.[84] In these western trials as much as 16 to 28 per cent of the long hay was not eaten by the lambs. When hay of good quality is fed in racks that prevent wastage, the saving through chopping or grinding will not average as much as in these trials. If hay is ground for sheep, it should not be ground too fine, for such a product is very dusty.

Whether it will pay to chop or shred dry corn fodder or stover or sorghum forage for sheep will depend on the proportion they would waste if the roughage were fed uncut, and also on the cost of such preparation. In a Texas test chopping sorghum hay for fattening lambs slightly increased the gains and saved one-third the hay, while in Colorado and Oklahoma trials it did not pay to chop sorghum hay or fodder or Sudan hay for lambs.[85]

1288. Pelleting feed.—Several experiments have been conducted recently to determine the effects of pelleting the entire ration for fattening lambs, or of pelleting only ground hay or else the concentrates.[86] In most of the trials in which the entire ration has been pelleted the gains and feed efficiency have been increased by pelleting, especially when

pellets containing the proper proportion of concentrates and hay have been self fed. However, often the cost of grinding and pelleting the grain and hay has been so high that the feed cost per 100 lbs. gain and the net return have been decidedly lower. In some of the trials the cost of such preparation has been $12 to $15 per ton.

There seems to be more advantage in pelleting the entire ration when the roughage is of rather poor quality, than when good roughage is fed.

In New Mexico trials with fattening lambs and yearlings, the gains were more rapid on pellets made from a mixture of ground sorghum grain, molasses, and ground stemmy alfalfa hay than when good long hay and whole sorghum grain were fed.[87] However, the cost of processing the pelleted ration was as high as $13.86 per ton.

If fattening lambs are fattened on pellets containing a mixture of concentrates and ground hay, it is wise to supply a little good long hay. Otherwise, they may show a great desire for such roughage, and manifest this by gnawing on feed racks and bunks.

Grinding the grain and pelleting the concentrate mixture alone for fattening lambs has not usually been profitable,[88] or grinding and pelleting the hay.[89]

1289. Shelter.—Sheep are so well protected from cold by their fleeces that they do not need warm shelter. Even in the northern states, one thickness of matched boards will make a barn or shed sufficiently warm, except for winter lambs. In the drier sections of the West, often no winter shelter is provided other than a windbreak to protect the sheep from cold winds and driving storms. If they are kept dry, sheep will stand a great degree of cold with no harm. On the other hand, too-warm quarters are injurious, for sheep sweat badly in winter when kept in a warm barn, and they are then apt to catch cold.

Ample ventilation is of great importance, but drafts should be avoided. With sheep it is more important than with other livestock that they be kept dry. Sufficient light, good drainage, and conveniences for feeding are other essentials of a good sheep barn. The doorways should be wide, to avoid injury when many animals attempt to rush through at once, in true sheep fashion.

In late spring and early summer the flock should be sheltered from cold rains, if possible, for the exposure may be dangerous, especially to young lambs. Even in the South, sheep should be protected from winter rains.

In summer, if there is no natural shade in the pastures, a movable shelter should be provided for shade, or the flock should have access to a darkened but well-ventilated shed. A fringed curtain of cloth or sacking through which the sheep may pass, will help to keep out flies.

Fattening lambs or sheep have an excess of heat on account of their liberal rations and therefore need less shelter than do breeding ewes. A well-bedded shed, opening to the south into a well-drained yard, is ideal for winter shelter, except perhaps in the extreme northern states. In 5 Indiana tests lambs thus sheltered made as rapid and as cheap gains and returned more profit than others housed in a well-ventilated barn.[90] In 3 trials at the Wisconsin Station, where the winters are colder, lambs housed in a well-ventilated barn and turned out daily for exercise gained a trifle more rapidly than did others housed in an open shed, partly boarded up for additional protection.[91] The average cost of feed was only 4.6 per cent higher for the lambs in the shed.

In the plains states and westward, no shelter is usually furnished for fattening lambs, except perhaps a windbreak. Any slight saving in feed through providing sheds is not sufficient to justify the expense.

In Nebraska and Idaho tests, providing an open shelter did not increase the gains or decrease the feed required per 100 lbs. gain.[92] In 3 trials in eastern Oregon, lambs having access to an open shed made slightly larger gains than others fed in a yard with no shelter, and required 3 per cent less feed for 100 lbs. gain.[93]

Where there is considerable rainfall or snowfall in winter, a shed may make more saving in feed. For example, in a Missouri trial yearling wethers fed in a yard without shelter required 19 per cent more feed than others which had access to a barn.[94]

1290. Exercise.—Sufficient exercise is essential for breeding ewes in winter, to insure strong, healthy lambs. The ewes should have access to a dry, sunny yard, well protected from wind and storm. To induce them to exercise on all fair days, roughage may be scattered in small bunches over a nearby field. If the snow is deep, paths should be broken out with a snow plow. On stormy days the sheep should remain indoors, for wet fleeces dry slowly in winter, and ewes that are close to lambing are better off without undue exercise.

For fattening lambs or sheep, it is preferable to limit the exercise, because too much exercise may reduce the gains. In 3 New York trials lambs confined to a roomy pen in a well-ventilated barn gained a trifle more than others allowed to run out during the daytime in a small yard.[95] The feed cost per 100 lbs. gain was 4 per cent less for the confined lambs.

1291. Feed troughs and racks.—Grain and roughage should be fed separately to sheep, except when a mixture of grain and chopped or ground hay is used for fattening lambs. Grain troughs should have a wide, flat bottom, to make the sheep eat the grain slowly. Hay racks should be so built that chaff and seeds will not fall upon the necks of the sheep and injure the quality of the wool. Combination grain-and-hay racks are satisfactory, if properly constructed. About 15 to 18 inches of linear feed trough and rack space should be provided for each ewe and 12 to 15 inches for each fattening lamb. Sheep are commonly fed hay and any other feeds twice a day.

EXERCISE IS ESSENTIAL FOR THE EWE FLOCK

If the ewes do not secure plenty of exercise, they are apt to have weak lambs. In winter the ewes may be forced to exercise by scattering roughage over a nearby field. (From Wisconsin Station.)

1292. Wool production.—The composition and structure of wool have been discussed in Chapter X. (314) It has also been there shown that adverse conditions, such as sickness, undue exposure, or a decided lack of feed, will not only

decrease the yield of wool but will also injure the quality.[96]

By proper culling of the flock of breeding ewes and using the weight and quality of the individual fleeces as one basis of selection, a marked improvement can be made in the annual yield of wool.[97] The first year's fleece of a ewe is usually a less reliable index of the fleece weight during succeeding years than the fleece of the second or third year.

The tendency in the case of certain breeds to place undue emphasis on wool covering over the face, ears, and legs is undesirable. A covering of wool around the eyes is a distinct disadvantage, especially under range conditions. Frequent clipping around the eyes is necessary, so that such sheep can see to eat and drink.

Even then, ewes with covered faces are less productive than open-faced ewes. In trials by the United States Department of Agriculture in Idaho, ewes with open faces produced 11 per cent more pounds of lamb a year than those with covered faces.[98] This was in spite of the fact that all ewes that were apt to become wool-blind were clipped around the eyes 3 times a year. The ewes with covered faces produced but a trifle more clean wool a year, only one-twentieth of a pound more, on the average.

Interesting experiments have been conducted in Wyoming to find whether protecting range sheep with canvas coats or rugs during winter would increase the yield or quality of the wool enough to justify the expense.[99] The coats appreciably increased the yield of wool, on the scoured basis, but the life of the coats was too short and the sheep lost too many of them to make the practice profitable.

1293. Shearing sheep.—Sheep are usually shorn in the spring after the weather has become fairly warm and settled. It is unwise to shear them too early, as they need the covering of wool to protect them from cold rains and snows. On the other hand, when shearing is delayed unduly, the sheep suffer from the heat and are troubled more with maggots about the breech, owing to the wool becoming foul.

Sheep should not be shorn when the fleeces are wet or even damp, as the wool is then apt to mildew. The fleeces should always be tied with paper twine or a strand made from the wool. Binder twine or sisal twine should never be used, as the fibers adhere to the wool and cannot be dyed uniformly with the wool. In branding sheep, a scourable branding paint should be used.

In hot climates sheep are often shorn twice a year, so they will be more comfortable. In Texas experiments shearing range ewes twice a year slightly increased the yield of wool, but hardly enough to offset the lower price received for the shorter fleeces.[100] The percentage of lambs born was not increased appreciably by shearing the ewes twice a year, but the death loss was reduced a trifle. Where the range is infested with shrubs like cat's-claw, which tear long wool, shearing twice a year is advisable.

Lambs and sheep that are to be fattened for market are often shorn either before being placed on feed or during the early part of the fattening period, to stimulate their appetites and make them more comfortable. Several experiments have been conducted to compare the results from fattening shorn and unshorn lambs.[101] These tests have shown that unless the weather is so warm that they are uncomfortable, unshorn lambs or other sheep will usually make practically as large and economical gains as if shorn.

In very cold weather shorn lambs may make slower gains and require slightly more feed per 100 lbs. gain. Before shearing, one should find the probable difference in price between fat shorn and unshorn sheep, and also know about how much wool he will secure by shearing and the price it will bring.

QUESTIONS

1. State some of the important advantages of sheep production under farm conditions.
2. Why must some Merino blood be retained in the flocks on the western ranges?

3. Give an example of the improvement that can be made by the use of a purebred ram on common ewes.
4. Why are lambs that are not retained for the breeding flock practically never carried over to the second year?
5. What have experiments shown concerning the importance of good roughage for breeding ewes?
6. Discuss the protein requirements of ewes during various periods.
7. What percentage of protein in a ration (on the air-dry basis) is needed by fattening lambs?
8. Is the quality of protein important for sheep fed good roughage?
9. Discuss the use of urea in feeding sheep.
10. Discuss the addition of a protein supplement to a ration of grain and alfalfa hay for fattening lambs.
11. Should a protein supplement be added to a ration of corn silage, legume hay, and corn or other grain for fattening lambs?
12. Compare the requirements of pregnant ewes and fattening lambs for total digestible nutrients or net energy.
13. What have experiments shown concerning the addition of fat to rations for fattening lambs?
14. What minerals need consideration in feeding sheep under usual conditions?
15. Discuss the salt requirements of sheep.
16. Under what conditions should a calcium supplement be added to sheep rations?
17. Are any trace mineral supplements needed for sheep in your area?
18. Discuss the water needs of sheep.
19. What have experiments shown concerning the use of the following for fattening lambs: (a) Antibiotic feed supplements; (b) arsonic supplements; (c) surfactants; (d) stilbestrol.
20. Discuss: (a) Grinding grain for sheep; (b) chopping or grinding roughage; (c) pelleting feed.
21. Discuss the requirements of sheep for shelter.
22. Compare the requirements of breeding ewes and of fattening lambs for exercise.
23. On what basis would you cull a flock of breeding ewes?
24. Discuss the shearing of sheep and of fattening lambs.

CHAPTER XXXI

FEEDING AND CARING FOR SHEEP AND LAMBS—FATTENING LAMBS—GOATS

I. The Breeding Flock; Raising the Lambs

1294. Essentials of successful flock management.—Intelligent management and proper care are even more necessary for success in sheep production than with the other classes of livestock. Yet, sheep are not hard to raise, once their relatively simple requirements are understood. Some of the most important points in successful flock management are: (1) Plenty of good pasture throughout the growing season; (2) proper feed and care of the ewes during winter, before and after lambing; (3) control of parasites; (4) producing the kinds of lambs that are in demand and having the lambs ready for market at the time of year when prices are high.

Order, regularity, and quiet are of prime importance in the management of sheep. The flock should always be cared for by the same attendant, who moves among them quietly, giving notice of his approach by speaking in a low voice and closing doors and gates gently. Cleanliness is essential, for sheep are fastidious, and dislike eating from dirty feed racks or troughs.

Unless stated otherwise, the discussions in this chapter concerning the feeding and care of sheep apply mainly to flocks kept under farm conditions. The production of sheep on the range is considered later in the chapter. (1325) Finally, the fattening of feeder lambs, especially those from the western ranges, is discussed in some detail. (1326–1337)

1295. Importance of good pasture.—For efficiency and economy in sheep production, an abundance of good pasture is essential for the flock throughout the growing season. Good pasturage is not only very important in keeping sheep thrifty, but also it is far cheaper than harvested feeds.

The economy of pasture is well shown by Indiana experiments with ewes and lambs, conducted during 3 pasture seasons.[1] Unweaned lambs made larger gains and reached better market finish when on good pasture with their mothers, without grain feeding, than when the ewes were fed in a dry lot, without pasture, on an excellent ration of alfalfa hay, corn, and oats. This was true even when the lambs in the dry lot were fed plenty of corn and alfalfa hay in a lamb creep. The cost of feed eaten by lambs and ewes, for each 100 lbs. gain made by the lambs, was only $2.83 for the lambs on pasture, in comparison with $16.82 for those in the dry lot.

1296. Pastures for sheep.—Permanent pastures or fields in the regular crop rotation are used most commonly for farm flocks of sheep. This is because such pastures generally provide forage at lower cost and over a longer season than annual pasture crops like rape or Sudan grass. Temporary pasture crops may be very useful in furnishing forage when other pastures are scanty during midsummer drouth. However, good pasture for this period can often be provided most readily and economically by using for pasture the second growth of mixed legumes and grasses on an early-cut hay field. (382)

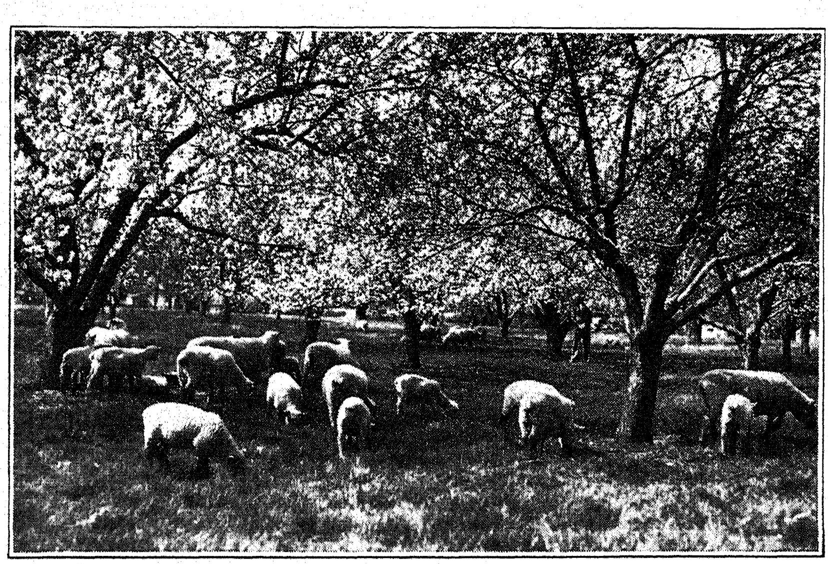
Detailed information has been presented in Chapter XIII on the fertilization, improvement, and management of pastures. The various pasture crops adapted to different regions have been discussed in Chapters XVI, XVIII, and XIX. It has been emphasized in these chapters that in most humid regions suitable mixtures of legumes and grasses are far superior to grass alone for pasture.

Such mixtures provide more nutritious forage than grass alone. Even more important, they furnish good feed over a longer period, especially in midsummer when such a grass as Kentucky bluegrass makes little growth.

Among the high-yielding pasture mixtures are alfalfa with bromegrass or timothy, Ladino clover and grass, or lespedeza and grass. The superiority of such mixtures over grass alone for sheep pasture is well shown by Michigan and Illinois tests.[2] In 3 Michigan trials the average liveweight gain of sheep per season was 362 lbs. per acre on alfalfa-bromegrass pasture and 309 lbs. on alfalfa-orchard grass pasture, in comparison with only 54 lbs. on orchard grass alone. In the Illinois tests the gain per acre on alfalfa-bromegrass over a 5-year period was nearly twice as great as on bromegrass alone.

Mixtures of alfalfa or clover with grass provide much safer pasture for sheep than the legumes alone, because there is far less danger from bloat. Nevertheless, in pasturing such mixtures, the precautions emphasized before should always be taken. (49) Even with proper care, animals occasionally bloat, especially on sultry days following a rain. Immediate attention is then necessary to save the afflicted animals. One of the methods of treatment suggested later should then be used. (1298)

The pasture season can often be extended by using winter grain for pasture in late fall and early spring. In the southern states, winter grain or other winter pasture crops will furnish good pasture during most of the winter.



Good Pasture Essential Throughout the Season

For efficiency and economy in sheep production, an abundance of good pasture is essential from early in the spring until late in the fall.

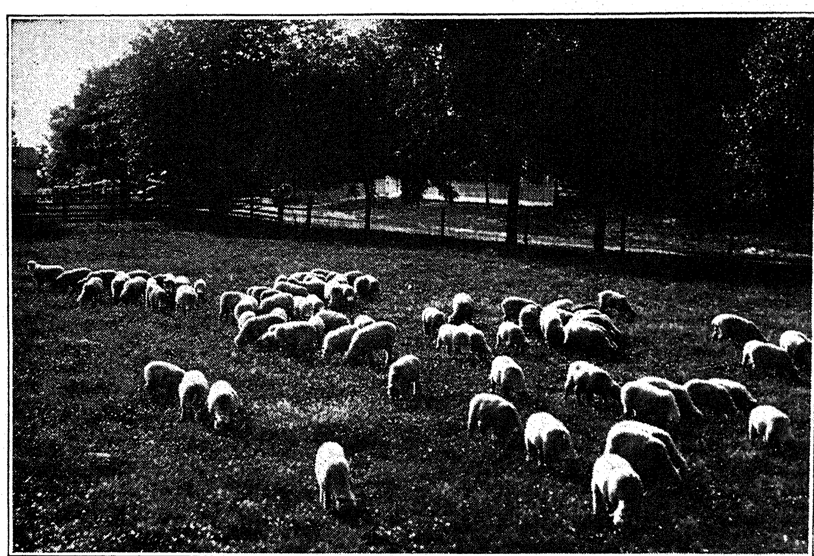
The importance of such pasture for early lamb production is shown by Georgia tests.[3] Lambs pastured with their dams on wheat pasture gained 60 per cent faster, to weaning time, than did lambs on permanent pasture. The use of such clean temporary pasture is also important in helping to prevent trouble from internal parasites.

1297. Pasture management for sheep.—Instead of keeping the sheep on one large pasture for the entire season, it is much better to divide the area into fields of such size that the sheep can be changed from one to another at frequent

intervals, after they have grazed an area thoroughly. This will reduce the trouble from internal parasites, and it will also utilize the pasture more fully, since rotational grazing tends to increase the yield of forage. (376) Rotational grazing is especially advantageous with such pasture combinations as alfalfa and bromegrass, or Ladino clover and grass.

As sheep relish most weeds and browse eagerly on sprouts and brush refused by other stock, small farm flocks will help protect them from dogs. Shade should be provided in the pasture. If there are no trees, a cheap movable shade should be made. This should be placed on the poorer spots in the field, so the droppings of the sheep will enrich them.

1298. Treatments for bloat.—If the bloating is not too severe, a drench of not to exceed a tablespoonful of formalin or of bicarbonate of soda in half a pint of warm water may be given to stop the gas production.[4] Sometimes a pint to a



Mixed Legume and Grass Pastures Are Ideal for Sheep

There is far less danger from bloat on mixed legume-and-grass pasture than on legumes alone.

can glean much feed from such sources and at the same time help in cleaning up the farm, especially lanes and fence corners. The wise flockmaster will always fully utilize all such feed, including stubble and stalk fields and the aftermath on meadows, thus reducing the cost of feed. Sheep prefer reasonably short grass to rank growths, and will eat weeds much better while they are young.

It is a good plan to have the pastures so located that the sheep can return to the barn for night shelter. It is then easier to inspect the sheep daily so that any trouble may be discovered, and it quart of warm milk is administered instead. Another treatment is to fasten a stick in the sheep's mouth, like a bit, by a cord tied back of the head. Chewing on the stick tends to cause belching, and enables the animal to get rid of the gas.

Severe bloat can sometimes be relieved by forcing a piece of one-half inch or smaller hose down the animal's gullet and into the rumen, to let the gas escape. As a last resort, a trocar or small knife should be used to tap the rumen.

1299. The ewe flock.—Profits from sheep depend largely upon having a flock of ewes that are carefully selected and

properly culled. The ewes should be healthy and vigorous, with deep, wide, roomy bodies, good teeth, sound udders, and high-quality, dense fleeces. They should be good milk producers and also be of good size for their breed, for under-sized ewes produce less wool and less weight of lambs per year.[5] However, they should not be too large or coarse, or their lambs may be too large to meet the market demands, before they are fat enough for slaughter. Per 100 lbs. of liveweight, small ewes may produce as much or more weight of lambs and wool as do larger ones, though their production per head is lower.[6]

Before the breeding season in the fall, the flock should be carefully culled, and all ewes discarded which are non-breeders or poor milkers, or which are otherwise unprofitable. These should be replaced by the most promising individuals raised in the flock. The ewes retained should not be selected by looks alone, for the thinnest ones may have been brought to this condition by a heavy milk flow. The only efficient method of selection is to keep a simple flock record, in which are recorded the ear-tag or ear-notch number of each ewe, the weight of fleece produced, the number of lambs raised, and the weight of the lambs at weaning time or when marketed. As a rule, good ewes should be retained as long as they are productive. In farm flocks most of the ewes are disposed of when 6 to 7 years of age.

Although well-grown ewe lambs will usually come in heat at 6 to 9 months of age, most sheepmen prefer to postpone breeding for a year, so that the ewes will have their first lambs when about 2 years old. Experiments have shown, however, that under favorable farm conditions a partial extra lamb crop can be secured by breeding ewe lambs of the earlier-maturing mutton breeds, if they are well grown and fed liberally.[7] Only a 60 to 70 per cent lamb crop will usually be secured the first year from ewes bred as lambs, and their lambs will not be so thrifty or so large at weaning time as lambs from older ewes.

Ewes bred as lambs generally reach the same size as those first bred as yearlings, but they are slower in maturing. In later gestations they produce as many and as large lambs as ewes first bred as yearlings. At 5 or 6 years of age the ewes bred as lambs will usually have raised an appreciably greater total weight of lambs. Breeding ewe lambs is not advisable in purebred flocks or under range conditions.

1300. Date of lambing; gestation period.—To secure the best prices for farm-raised fat lambs, they should be ready for market either before or after the rush of grass-fat lambs from the western range states. If warm quarters and plenty of good legume hay and grain are available, early lambs, dropped before April first and marketed not later than July, are usually most profitable, for they commonly sell at a higher price per hundredweight than later lambs. Such lambs are less troubled with internal parasites, and another advantage is that the lambing season comes before the rush of spring work.

Ewes which lamb early need plenty of good feed in winter and the lambs should be fed grain before pasture is available in the spring. The production of "spring lambs" and of "hot-house lambs" is discussed later in this chapter.

Where grain and good hay are expensive or if the shelter is not suitable for early lambs, it is best to have the lambs born in April or May and to sell them in autumn after the rush of western lambs to market.

The average length of the gestation period of ewes is 145 to 147 days, according to various authorities.[8] It is longer for Merino and Rambouillet ewes than for ewes of the mutton breeds, averaging about 152 days for the former breeds. For Southdowns and Shropshires, it is usually slightly shorter than for the larger mutton breeds.

1301. Twin lambs.—Under favorable conditions where good care can be given to the ewes and lambs, it is important to secure a high lambing percentage. To obtain this, a large proportion of the ewes must have twin lambs.

Twin lambs will generally gain less

than singles while nursing, as they get less milk. However, they tend to make up some of the difference later, if they have good pasture.

In Ohio studies, an average of 198 lbs. in market weight of lambs was secured from ewes raising twin lambs, in comparison with 104 lbs. for ewes with singles.[9] This shows that twins are certainly advantageous under favorable farm conditions.

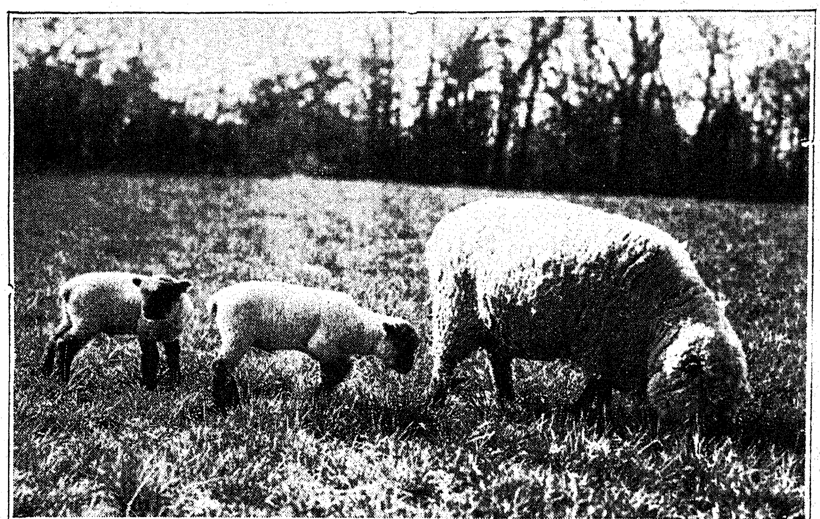
On the western ranges, where less attention can be given to the individual ewes, single lambs have usually been preferred. However, experiments show that even under range conditions, twin lambs are desirable if pasture and feed conditions are average or better, except for aged or for immature ewes.[10] A decidedly larger average total weight of lambs was produced by ewes with twins, than by ewes having single lambs.

1302. Breeding time; flushing the ewes.—The natural breeding season for most breeds of sheep is during the late summer and autumn. Ewes will usually begin to come in heat after the first cool nights, and the periods of heat recur approximately every 16 days, unless the ewes conceive.

It is a common belief among experienced sheepmen that ewes which are "flushed" at breeding time, or fed so that they are gaining in weight, are more apt to produce twins and triplets than those which are in poor flesh, and that they also breed earlier and more nearly at the same time. In most, but not all, of the experiments to study the effect of flushing ewes, the practice has proved decidedly beneficial.[11]

Any advantage of flushing can undoubtedly be gained by furnishing the ewes with excellent pasture previous to and during the breeding season. If such pasture cannot be provided, it may be well to feed them a small amount of grain at this time. Liberal feeding before breeding time is especially needed if the ewes have run down in flesh during summer, as is common with ewes having large milk flows, even though they have had good pasture. If ewes have been fed inadequately after their lambs were weaned, and have consequently run down in condition, many of them will fail to come in heat or they may fail to conceive.

Attempts to secure earlier lambs by injecting hormones into ewes have usu-



Twin Lambs Most Profitable under Favorable Conditions

If the ewes and lambs are well fed, twin lambs will gain nearly as rapidly as single lambs.

ally not been successful.[12] Where such treatment has brought ewes into heat, in most cases they have not become pregnant when bred.

In a Kentucky experiment ewes kept at a cool temperature in an air-conditioned room in summer, bred nearly 8 weeks earlier than those not so housed.[13] This indicates that where one wishes to produce early lambs, it may help to have plenty of shade in the pasture for the ewes in summer, and a cool, well-ventilated barn for night shelter.

Whether the shorter days in the fall are of importance in bringing ewes into heat, seems to be an unsettled question. The results of experiments on length of day have differed.[14]

1303. The ram.—A well-built, vigorous purebred ram of good breeding should be selected for the flock, and then be so fed and cared for that he will remain potent. A vigorous ram will serve 40 to 50 ewes a season, if allowed to run with them all the time during the breeding season, as is the common practice. Where "hand coupling" is practiced or if the ram is turned with the ewes only a short time daily, more ewes can be bred to one ram. A well-grown ram lamb may be bred to 12 or 15 ewes without reducing his future usefulness, if he is properly fed and handled.

During most of the year good roughage alone should be sufficient to keep the ram in proper condition. Pasture should be provided in summer, if possible. In winter he should be fed legume or mixed hay, and perhaps silage in addition. Mangels or sugar beets should not be fed, as they may tend to produce urinary calculi, or stones. (632)

For a month before the breeding season, the ram should be given about a pound a day of the same sort of concentrate mixture that is fed the ewes. It is also a good plan to continue the feeding of the concentrate allowance during the breeding season, if it can be done conveniently. The ram should not be allowed to run down seriously at breeding time through insufficient feed or over use. On the other hand, he should never become fat. In purchasing a ram, one that has been highly fitted, or fattened, for shows should be avoided, for over-fitting may result in low fertility.

It is a good plan to keep the ram away from the ewes, except during the breeding season, so that he cannot annoy them. However, he needs exercise to keep in vigorous condition. If a pasture paddock is not provided for him, it is better to let him run with the flock throughout the year than to confine him.

The fertility of rams may be lowered by very hot weather.[15] Where early lambs are desired, it may be desirable to keep rams as cool as possible by shearing them 3 or 4 weeks before the breeding season.

1304. Feeding the ewes in the fall.—Plenty of good pasturage should be provided for the ewes in the fall. Where the weather is mild, considerable of their late fall and winter feed can come from winter rye or wheat pasture or from grass pasture which has been allowed to grow up in the fall.

Ewes can often get much of their fall feed by cleaning up stalk and stubble fields, thus using feed that would otherwise be wasted. It is best to use such forage early, before fall rains and frost have lessened its value, and to leave other pasture for later grazing. If there is a shortage of pasture in the fall, care should be taken to supply sufficient hay or grain to keep the ewes thrifty. Rape furnishes excellent feed late in the fall.

1305. Winter feed and care.—If the ewes go into the winter in thrifty condition and are then fed as much good legume or mixed legume-grass hay as they will eat, with or without silage or roots in addition, they will usually need no grain or other concentrates until 4 to 6 weeks before lambing. Then not more than 0.50 to 0.75 lb. per head daily is commonly required, and the ewes should not be allowed to become really fat. An experienced shepherd knows that the only safe way to determine the condition of a sheep is by feeling of its back. If he finds that the ewes are not thriving, he will feed them more liberally.

The ewes should be wintered so that they will gain 20 to 30 lbs. during preg-

nancy, and be in medium flesh and vigorous condition at lambing time. Experiments have shown that insufficient feed or an unbalanced ration, especially during the latter part of pregnancy, often results in weak lambs and a scanty flow of milk.[16] Ewes that are seriously underfed at this time may show but little mothering instinct when their lambs are born, and may have very little milk for them.

On the other hand, it is not only unnecessarily expensive but also unwise to feed breeding ewes so liberally that they are really fat at lambing time.[17] They are then apt to have more difficulty in lambing and may also produce weak lambs.

Both ram lambs and ewe lambs intended for the breeding flock should be so fed the first winter that they will grow steadily, but they should never receive a fattening ration.

For winter shelter, dry, well-ventilated quarters should be provided, with wide doorways and convenient feed racks. (**1289, 1291**) It is best to divide large flocks into groups of sheep of similar size and condition, so that the amount of feed can be suited to the needs of each group. For example, yearling ewes will need a little more feed than mature ewes, as they are still growing. Exercise in winter is essential for breeding ewes, as has been emphasized previously. (**1290**) Salt and plenty of water should always be provided for the flock.

1306. Rations for ewes.—As a guide in selecting satisfactory and economical balanced rations for breeding ewes, several example rations that are adapted to conditions in various sections are given in Appendix Table VII. These are balanced according to the Morrison feeding standards, and should produce satisfactory results. Ewes wintered in the open in the northern range states, without shelter, may require somewhat larger amounts of feed than stated, due to the exposure.

The amounts of roughage stated in these rations are the amounts actually eaten, after deducting the wastage.

1307. Hay, silage, and other roughages for ewes.—The importance of high-quality hay and other good roughage in wintering pregnant ewes has been emphasized in the previous chapter. (**1264**) The lamb crop is apt to be very unsatisfactory if most of the roughage for the ewes is straw or low-grade hay. Detailed information is given in Part II concerning the value for sheep of the various kinds of hay and other roughages.

If possible, the ewes should be fed a liberal amount of good legume hay or mixed hay high in legumes. Such hay is rich not only in protein, calcium, and vitamins, but it is also laxative. Moreover, it is usually more economical to supply the necessary protein for the ewes by feeding legume hay than by purchasing considerable amounts of protein supplements.

For sheep, grass hay is best used along with some legume hay. In South Dakota experiments the results in wintering ewes were as satisfactory with about 1 lb. of alfalfa hay per head daily plus what good bromegrass or wheatgrass hay they would eat, as on alfalfa hay as the only roughage.[18] The feed cost was less on the combinations.

Late-cut grass hay is unsatisfactory for sheep, for it is not only unpalatable and low in nutrients, but also it may cause serious constipation. Early-cut and well-cured grass hay, though inferior to legume hay, may be used satisfactorily as the only roughage, when properly supplemented with protein and minerals. (**566**) Well-cured corn or sorghum fodder, harvested while the leaves are still green, is preferable to late-cut grass hay. Straw alone or straw with corn silage or sorghum silage is unsatisfactory as the roughage for ewes.

Corn silage, sorghum silage, or hay-crop silage is an excellent addition to a ration for wintering ewes. It aids in preventing constipation and in keeping the ewes thrifty, especially when little or no legume hay is available. Adding silage to an abundance of good alfalfa hay does not usually make much difference in the thrift of the ewes or the vigor of the lambs. The economy of using silage under such conditions will depend on the relative cost of silage and of alfalfa hay,

good corn silage being worth about one-half as much per ton as such hay. Though roots are excellent for ewes, silage is a much more economical feed under conditions in the United States.

It is best to use corn or sorghum silage along with good legume or mixed hay, instead of feeding it as the only roughage.[19] A good plan is to feed at least 1 lb. of hay to each 2 to 3 lbs. of silage. However, corn silage has even been satisfactory as the only roughage for pregnant ewes, when a sufficient amount of protein supplement has been fed and also a calcium supplement.[20]

Hay-crop silage of good quality is also satisfactory as the only roughage for ewes. (**440**) Because of the lack of grain in such silage, it may be necessary to feed a little grain, in order to keep the ewes in the desired condition. However, no protein supplement is needed with hay-crop silage.

In the southern states special winter pasture crops can furnish much of the feed for ewes and early lambs. In 3 Mississippi trials the average net return per ewe was $11.20 for ewes wintered chiefly on temporary pastures, in comparison with $6.12 for ewes in dry lot.[21] In Missouri trials with ewes bred for early lambs and wintered on good pasture plus hay when the weather did not permit grazing, it did not pay to feed concentrates previous to lambing.[22]

1308. Concentrates for ewes.—Not only the amount but also the kind of concentrates required by breeding ewes will depend on the kind of roughage that is used. If a liberal amount of legume hay is fed, the concentrates may be chiefly or entirely grains, such as oats, corn, barley, or the grain sorghums.

Oats are highly esteemed as a feed for ewes and are often fed as the only concentrate with legume hay. Corn is considered too fattening by many shepherds to be used as the chief concentrate. They prefer bulky mixtures containing considerable oats or wheat bran. However, if plenty of protein is furnished by legume hay or other protein-rich feeds and the ewes are not over-fed on corn so that they become unduly fat, corn can be used satisfactorily as the chief or only grain.[23] Because corn is higher than oats in total digestible nutrients and net energy, less corn than oats is needed to keep the ewes in suitable condition.

Barley, wheat, and the grain sorghums are all satisfactory for breeding ewes, when fed in suitable mixtures.

Unless a liberal amount of legume hay is fed to the ewes, it will be necessary to include a sufficient amount of a protein supplement in the concentrate or grain mixture to balance the ration. Several concentrate mixtures that are suitable for feeding with various combinations of roughage are given in Appendix Table VII. The values of the various protein supplements have been discussed in chapters of Part II. Wheat bran and linseed meal are probably most widely used for the breeding flock in the United States, but other supplements are satisfactory when they are more economical. If there has been trouble from the "stiff lamb disease" in the flock, it is important to include wheat bran or wheat germ meal in the concentrate mixture for the ewes and the lambs. (**1315**)

Under usual conditions it is most economical to winter ewes on all the roughage they will eat, with only enough concentrates to keep them in proper condition. When hay is high in price in comparison with grain, it may be economical to restrict somewhat the amount of hay fed to ewes, and to increase the allowance of grain or other concentrates instead. Judging from the results of Kentucky, Michigan, and Montana trials, 100 lbs. of grain will replace 175 to 200 lbs. of hay when thus fed.[24]

If ewes are fed good roughage, there is no advantage in adding a vitamin A or carotene supplement to the winter ration.[25] (**1281**)

1309. Supplementing winter range.—Where ewes are wintered on mature and weathered range forage, experiments have shown that the feeding of a suitable supplement will usually be profitable. It will keep the ewes in thrifty condition, will bring a greater lamb crop, will increase the weights of the lambs at

birth and at weaning, and will produce more wool. The kind of supplement needed will depend on the actual deficiencies in the range forage. If it is low in phosphorus, a phosphorus supplement is essential. Commonly, such forage is very low in protein, and it may not supply enough total digestible nutrients or net energy to keep the ewes from running down in weight.

In Montana experiments it was generally profitable to feed ewes on winter range 0.3 lb. per head daily of pelleted supplements which supplied not only protein and energy, but also phosphorus and vitamin A.[26] Under their conditions, the results were about as good with low-protein pellets, consisting mostly of grain and molasses, as with high-protein pellets, and the low-protein pellets were cheaper.

In Utah trials with ewes wintered on a saltbush range, the chief need in the supplement was for protein and for phosphorus.[27] Feeding 0.2 lb. per head daily of a 40 per cent protein supplement, either all winter or only the last half, was superior in a South Dakota trial to feeding 0.2 lb. of a 20 per cent protein supplement all winter.[28]

1310. Lambing time.—Proper attention to the flock at lambing time is essential, for heavy losses of lambs often occur when care is lacking. The shepherd should therefore be close at hand to give assistance to any ewes or lambs that need it. In order to know when the ewes are due to lamb, in farm flocks it is wise to keep a breeding record, showing when each was bred. Just before lambing, little grain or other concentrates should be fed, so as to reduce the danger of milk fever. Any tags of long and loose wool about the rear and udder of each ewe should be removed at this time.

It is best to put each ewe in a "claiming" or "lambing" pen immediately after lambing or shortly before. This should be kept bedded with clean straw. The ewe should remain here for 3 or 4 days after lambing, until the mother and her offspring become thoroughly accustomed to each other and the lambs are strong enough to look out for themselves among the flock. The lambing pens may be made by setting up panels 4 feet long, hinged in pairs, along a warm side of the stable. In very cold weather burlap sacks hung on the panels will help keep new-born lambs warm.

Simple triangular lamb brooders, set in a corner of the lambing pen and heated with a heat lamp, will prevent the new-born lambs from becoming chilled in very cold weather.[29]

During lambing the ewe should not be disturbed unless assistance is needed. When the ewes have been fed and managed properly during pregnancy, most of them will lamb with little or no help. Weak lambs sometimes need special attention to save them. A lamb that seems almost lifeless at birth may often be restored by quick attention. Any mucus should be cleaned from the nostrils and mouth. To start breathing, the lamb should be slapped on both sides of the body just back of the shoulders or rubbed briskly with a handful of straw or a burlap bag. Occasionally, it may be necessary to warm a chilled lamb.

If a lamb is unable to nurse within a half-hour after birth, it should have patient assistance. Soon after birth, the stump of the navel cord should be immersed in tincture of iodine to prevent infection with navel ill or other disease.

A ewe that refuses her lamb will usually accept it if they are kept together in a lambing pen, and the lamb helped to suckle a few times. A stubborn ewe may be tied so that she cannot prevent the lamb nursing. In case a ewe loses her lamb, she may often be induced to adopt one of a pair of twin lambs by first sprinkling some of her own milk over it. Still more effective is tying the skin from the dead lamb upon the back of the one to be adopted.

1311. The percentage of increase; weights of lambs at birth.—The number of lambs raised per 100 ewes of breeding age, or the percentage of increase, will vary widely depending on the conditions under which the sheep are kept and also depending on the breed. Fine-wool sheep are less prolific than the mut-

ton breeds, and the percentage of increase can be much greater with farm flocks than under range conditions.

In the western range states, the average number of lambs raised to market age for each 100 breeding ewes varies from less than 60 to 80 or over.[30] In certain fine-wool flocks in Ohio, an average of 80 to 82 lambs were raised per 100 bred ewes.[31]

With ewes of the mutton breeds, kept under excellent conditions, the percentage of increase can be much greater than this. For example, during 24 years at the Wisconsin Station the average number of live lambs born per 100 ewes of various mutton breeds was 161.[32] Such a high percentage of increase can be secured only when the ewes are kept under excellent conditions. Also, to develop a flock that will have a high percentage of increase, ewes must be bred and selected for ability to produce twin lambs.

The percentage of increase of ewes tends to grow greater until they reach the fifth or sixth year. This is doubtless due somewhat to discarding the poorer breeders as 3-year-olds. The larger ewes of a given breed tend to have a greater percentage of increase and their lambs tend to be larger.

Lambs that are large for the breed at birth are usually stronger than small lambs, the death loss is less, and the lambs tend to weigh more at weaning time.[33]

In Wisconsin studies the average birth weights of single lambs were as follows for the various breeds: Shropshire, 9.5 lbs.; Southdown, 9.2 lbs.; Hampshire, 10.6 lbs.; Cheviot, 9.5 lbs.; Dorset, 10.2 lbs.; and Oxford, 10.4 lbs. The average birth weights of the twin lambs were: Shropshire, 7.7 lbs.; Southdown, 7.7 lbs.; Hampshire, 8.2 lbs.; Cheviot, 7.7 lbs.; Dorset, 8.5 lbs.; and Oxford, 8.2 lbs.[32] The triplet lambs were somewhat smaller than the twins. In California studies the average birth weight of Rambouillets was 9.9 lbs.; of Hampshires, 9.3 lbs.; of Shropshires, 8.6 lbs.; of Southdowns, 8.7 lbs.; and of Romneys, 9.0 lbs.[34] In the Wisconsin studies the ram lambs averaged 0.5 lb. heavier at birth than the ewe lambs.

1312. After lambing.—Soon after lambing, the ewe should be given water with the chill removed, but should not be allowed to drink too much at a time. To avoid udder trouble, only a little grain should be fed for the first 2 or 3 days, although the ewe may have all the dry roughage she wishes. Close attention must be given for a few days to see that the lamb is taking milk from both sides of the udder. All surplus milk should be drawn, or better, a needy lamb helped to an extra meal.

As soon as the lambs are able to take more milk, the ewes should be fed liberally enough to insure a good milk flow, for lambs make the most economical gains when they are suckling. The ration should be fairly rich in protein, for the ewes are not only producing milk but are also growing wool, which is composed chiefly of protein.

If there is not enough roughage of high quality for the entire winter, some of it should be saved for feeding after lambing. If possible, plenty of legume hay should be fed, and also silage or other succulent feed. If there is little or no legume hay, it will be necessary to include in the grain mixture more of such feeds as linseed meal, soybean oil meal, or wheat bran.

Several concentrate or grain mixtures are recommended in Appendix Table VII that are suitable for ewes nursing lambs. With good roughage, 1 lb. or slightly more of grain mixture per head daily should be sufficient for the ewes at this time. As soon as good pasture is available for the ewes, they no longer need grain, hay, or other harvested roughage.

All the lambs should be docked when 1 to 2 weeks old. The ram lambs not intended for breeding should also be castrated at this time, except perhaps when the lambs are to be marketed at not over 4 to 5 months of age on a market that does not discriminate against ram lambs of this age.

Up to this age, ram lambs may make fully as rapid gains as wether lambs, and also there is little difference in the quality of carcass.[35] However, on

the large markets ram lambs often sell at a discount of $1.00 per hundredweight, even when no older than this.

When older than 4 or 5 months, ram lambs yield carcasses of distinctly lower value than wethers, as their carcasses are heavy in the fore quarters and contain a smaller proportion of valuable cuts. In hot-house lamb production, the ram lambs are not commonly castrated.

1313. Milking qualities of ewes.—In building up a profitable flock it is highly important to select ewes on the basis of their milk production and nursing qualities, as well as on type and conformation. The rate of gain made by a lamb during the suckling period depends more largely on the amount of milk the dam produces than on any other factor.

In recent Arkansas studies the total milk produced by Hampshire ewes in 12 weeks ranged from an average of 95 lbs. for the lowest yielders to 217 lbs. for the best producers.[36] The daily milk yield was highest the first 4 weeks, declined rapidly the next 4 weeks, and then fell more slowly.

For each additional pound of milk yielded by the high producers, the average daily gains of their lambs were 0.16 lb. more a day than of the lambs of the poor milkers. The lambs getting the most milk gained 59 per cent more from birth to 12 weeks than the lambs of the low milk producers. In a New Hampshire study there was even a larger difference.[37]

Ewe's milk is usually much richer in fat and protein than is cow's milk, having an average of 6.9 per cent fat and 6.5 per cent protein. In studies at the Idaho, New Hampshire, and Wisconsin Stations, the daily yield of milk by ewes of various breeds ranged from less than 2 lbs. to 7.5 lbs., and the fat content from 3.8 to 12.1 per cent.[38] There was a much greater range in fat percentage for the milk of ewes of the same breed than difference between the average composition for the various breeds.

In this country the milk of sheep is seldom used by man, but abroad, especially in certain mountain regions of continental Europe, it is extensively employed, both for direct consumption and for the manufacture of cheese. European milk sheep may yield 3 to 4 quarts of milk daily for 2 months after weaning their lambs.

1314. Pregnancy disease.—Pregnancy disease, also known as ketosis or lambing paralysis, is one of the most common causes of death of pregnant ewes in late winter and early spring, within a month of lambing.[39] It is somewhat similar to ketosis in cows, except that it affects a ewe before parturition, instead of afterward. (**1087**)

Pregnancy disease usually occurs only in ewes that are underfed during pregnancy, especially during the last month or two. The cause seems to be an insufficient supply of readily available carbohydrates, such as starch, to meet the need for energy in the rapid development of the unborn young. As a result there is a greater metabolism of fat in the body and an accumulation of certain normal products of fat metabolism, called ketone bodies, which are toxic when present in excess.

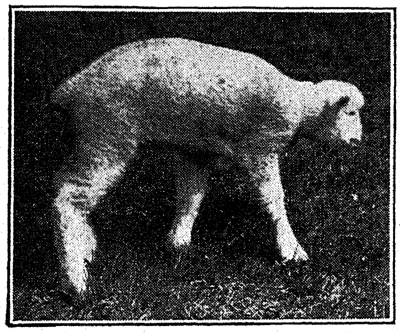
The disease is most common when ewes are fed poor roughage and no grain before lambing. Fortunately, there is generally little trouble from pregnancy disease when ewes are well fed before lambing, as advised in this chapter. It is more apt to occur in ewes bearing twins or triplets than in ewes bearing a single lamb, and it is more frequent in mature ewes than in two-year-olds. Close confinement, lack of exercise, or undue exposure to snowstorms or cold weather may tend to produce the disease. It practically never occurs when ewes are on pasture.

A ewe affected with the disease at first appears sluggish or sleepy. She is reluctant to rise and walks with an unsteady gait. Later, she becomes paralyzed and often lies with the head bent far backward. In an early stage of the disease, the ewe may be saved by hypodermic injections of a glucose solution by a veterinarian, followed by careful drenching with a solution of glucose, cane sugar, or molasses twice a day or oftener. Where the trouble has appeared in a flock, it may help to add molasses to the concentrate mixture fed all pregnant ewes.

Sufficient data are not yet available to prove whether the trouble can be prevented or cured by adding sodium propionate to the ration. As has been shown in Chapter XXVI, this is generally effective in ketosis of dairy cows. (**1087**) In a Maryland test, though

cortisone injection usually cures ketosis in cows, it did not seem to cure pregnancy disease in ewes.[40]

1315. Stiff-lamb disease.—Stiff-lamb disease, or white-muscle disease, is a strange disease of young suckling lambs, which usually becomes apparent when the lambs are 1 to 5 weeks old. The lambs that are affected become characteristically stiff. Some stiff lambs stagger around for several days and then gradually improve, but many become



A STIFF LAMB

Note characteristic gait. (From J. P. Willman, Cornell University.)

so stiff that they are unable to walk or to nurse without assistance. Death is probably not due to the disease itself, but, owing to starvation, the lambs become so thin and weak that they die or are killed by the owner. The disease is not common in most regions, and seems to occur more often in the northeastern states than in other districts.

Post-mortem examinations of stiff lambs shows that certain of the muscles have undergone degeneration, becoming whitish in color. Almost invariably, the disease affects the same muscles on the two sides of the body. The trouble is apparently due entirely to feed and not to any infection.

In experiments during 13 years at the New York (Cornell) Station, stiff lambs were produced experimentally each year when ewes were wintered on a ration of cull beans, oats, barley, and alfalfa hay of good quality.[41] The disease still occurred when the ewes had abundant exercise and when they were fed so that they did not become unduly fat.

In contrast to the results on this ration, not a single stiff lamb was produced by ewes which were fed a ration of wheat bran, oats, corn silage, and mixed clover-and-timothy hay. Farmers who had previously suffered severe losses from the disease reported much better results after changing to this ration or one which was similar.

The trouble was greatly lessened when considerable wheat bran was added to a ration that otherwise produced the disease, and it was prevented by the feeding of wheat germ meal to the ewes and lambs. Since wheat germ meal and wheat bran are rich in vitamin E, the effect of this vitamin was then tested. It was found that the disease can be prevented or cured by feeding rations containing liberal amounts of vitamin E or alpha-tocopherol (223).

Where there has been trouble from the disease, it is recommended that one-quarter to one-half pound per head daily of wheat germ meal be included in the concentrate mixture fed the ewes a few weeks before lambing, or that 50 per cent by weight of wheat bran be used in the mixture. In addition, the lambs should be fed wheat germ meal or wheat bran in a creep. Concentrated forms of vitamin E have also been found effective in preventing or curing the disease.

In some field trials vitamin E supplements have prevented the occurrence of stiff lambs, but not in certain others.[42] Other causes than a lack of the vitamin may therefore be connected with the trouble.

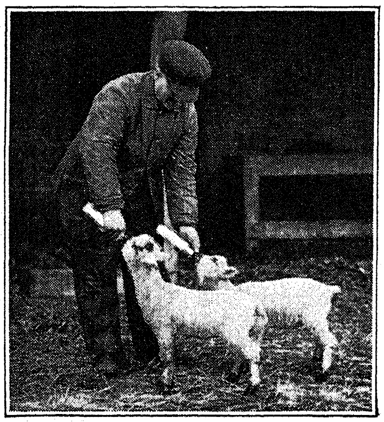
An entirely different type of stiffness in lambs is produced by a disease called arthritis.

1316. Orphan lambs.—If possible, a foster mother should be found for any orphan lamb. However, in case this cannot be done, the orphan can be successfully raised on cow's milk, though close attention is necessary the first month.[43] For the first 3 or 4 days the lamb should have some colostrum ewe's milk, if possible, by letting it nurse ewes whose lambs are not yet old enough to take all their milk.

The cow's milk should be whole, fresh, and warmed to approximately 100° F. It should be fed in a bottle with a suitable nipple that is carefully washed after each feeding. For the first day or two after birth, the lamb should be fed every 3 to 6 hours, only 2 to 4 tablespoonfuls being given at a time. After the lamb is 2 to 3 weeks old, it is not necessary to feed it more than 3 or 4 times a day. The lamb should be given other feed in addition to milk when it is about 2 weeks old. A suitable mixture is the one suggested in the following article for creep-feeding. (1317)

In some studies lambs that have received some colostrum have been raised successfully on a "synthetic milk," or milk replacer.[44] (1142)

1317. Raising the lambs.—During the suckling period of 4 to 5 months, well-fed lambs will make about two-thirds of the growth and the gain in weight that they will make during the entire first year.[45] Furthermore, the most economical gains are made at this time. It is thus very important that lambs be well fed during this period.



ORPHAN LAMBS

Care and patience are necessary to raise orphan lambs on a bottle.

Until pasture is ready in the spring, early lambs should be fed both grain and hay in a "creep," beginning when they are about 2 weeks old. Indiana experiments show that lambs fed grain in a creep at this time make larger and cheaper gains, reach a better finish, and return a greater profit than those not thus fed.[46] It may not pay to creep-feed lambs that are born less than a month before they go to pasture, as they will not learn to eat much feed by that time.

The creep is made by fencing off a corner of the barn with panels in which there are openings just wide enough so the lambs can pass through, while the ewes are kept back. Within the creep there should be a hay rack and a low, shallow grain trough with a board lengthwise above the trough to prevent the lambs from jumping into it. In this trough a suitable concentrate mixture is fed, only a little being sprinkled at first. Legume hay of choice quality should also be supplied. Fresh feed should be put in once or twice a day, and the refuse can be fed to the ewes.

An excellent mixture for creep-feeding lambs is corn, 20 or 30 lbs.; oats, 20 or 30 lbs.; wheat bran, 10 lbs.; and linseed meal or soybean oil meal, 10 lbs. After the lambs are 5 to 6 weeks old, there is no advantage in grinding most grains for them. (1286)

If the lambs are all to be fattened for market, grain alone may be used for creep-feeding, because the milk will furnish ample protein. A mixture of half corn and half oats is often used. In Indiana and Kentucky tests cracked corn produced as rapid or nearly as rapid gains, and also cheaper gains, than such a mixture as corn, oats, and linseed meal, or as more complex mixtures.[47]

Good pasture should be provided for ewes and lambs as early in the spring as possible. The change to pasture should be gradual, the flock being turned on pasture for only 2 to 4 hours at first. Letting them fill up on hay before being turned out to pasture the first time, helps prevent digestive disturbances. If there has been any trouble from the stiff-lamb disease, it is best to turn the lambs out only about 15 minutes at first. Shade and fresh water should always be provided ewes and lambs on pasture.

Ewes on good pasture need no grain or other harvested feeds. Also, with the possible exception of early lambs to be marketed as spring lambs at weaning, it does not generally pay to creep-feed lambs running with their dams on first-rate pasture.[48] On the other hand, if there is a shortage of pasture forage, the lambs should be supplied with grain or a suitable mixture in a creep.

Corn or a mixture of corn and oats is very satisfactory for creep-feeding to suckling lambs on pasture. In Kentucky trials cracked corn produced larger and more economical gains than a mixture of corn, oats, and linseed meal or a mixture of corn and a special commercial milk substitute.[49] Many sheepmen, however, prefer such a mixture as the one suggested previously.

During the summer a lamb on pas-

ture will consume nearly as much feed as a dry ewe, according to Nevada trials, and a ewe and her lamb will consume twice as much feed as a dry ewe.[50]

1318. Marketing lambs early; feeding after weaning.—Where farm lambs are raised under good conditions and with plenty of pasture, a large proportion of them should be fat enough for marketing when they reach weaning age. Especially in the case of early lambs, it is often most profitable to sell such lambs at this time.[51] Lambs thus marketed early, before the western range lambs reach the market, usually bring a considerably higher price per 100 lbs. than if marketed in late fall or in winter.

Lambs that are to be retained in the flock and those which are not sufficiently fat for market should be weaned at 4 to 5 months of age. This should be done for their own good as well as to allow their dams a rest before another breeding period. If possible, advantage should be taken of a cool spell in summer to wean the lambs, as they will then be more comfortable during this trying period.

The lambs should be so far separated from their dams that neither can hear the bleating of the other. For a few days the ewes should be held on short pasture or kept on dry feed in the yard, so as to reduce their milk flow. The udders must be examined, and, if necessary, as is often the case with the best mothers, they should be milked out a few times, so inflammation will not result.

It is especially important to provide fresh pasture, free from parasites, for the lambs after weaning. Profitable gains cannot be expected if the lambs are taken from their mothers and left on a pasture infested with parasites and where the feed is scanty.

Whether or not to feed grain to lambs after weaning will depend on the relative prices of grain and pasture and on the premium paid for well-fattened lambs. Ohio experiments have shown that if really good pasture is provided, the feeding of grain to lambs after weaning is not necessary for the economical production of well-finished lambs.[52] If first class pasture is not available for the lambs after weaning, it may be best to take them off pasture and fatten them in dry lot on a suitable ration.[53]

Ewe lambs to be retained in the flock need no grain when grazing is good. Ram lambs require grain during the fall to secure proper development, whether they are to be sold as lambs or retained until yearlings.

Ewe lambs being raised as flock replacements can be wintered satisfactorily on only legume or mixed hay, with other good roughage as available, if the supply is abundant and if they are well fed the second winter previous to lambing.[54] With poorer roughage, they should receive enough supplemental concentrates the first winter to keep them growing thriftily.

Under range conditions it is important to supplement winter range when necessary for proper growth of the ewe lambs.[55]

1319. Spring lambs.—Early lambs marketed from April to July 1 or early July are called "spring lambs" on the market. Raising spring lambs is of much importance in the southern and southwestern states and also in certain valleys of the West.[56] In the warmer districts the ewes can be maintained chiefly on pasture throughout the year, greatly reducing the cost of feed. Also, no expensive shelter is required.

Unless the ewes and lambs have excellent pasture, the lambs should be fed grain or a suitable concentrate mixture in a creep, so they will be ready for market when prices are best. The lambs should be well finished at 3 to 5 months of age, weighing 55 to 70 lbs.

Some farmers, especially in certain western districts, follow the plan of buying in the fall ewes which have been discarded from range flocks on account of age or poor teeth, and breeding them for the production of one crop of spring lambs. Such ewes must be fed good rations, including plenty of grain both before and after lambing, so they will be fat enough to sell well when their lambs are marketed, or a little later.

1320. Hot-house or winter lambs.—In certain sections of the eastern states there is a profitable market for "hot-house" or winter lambs. The term "hot-house" lambs does not mean that they are raised in artificially warmed quarters, but is used because they are produced at an unusual season and are therefore comparable to the out-of-season products of hot-houses. The market for hot-house lambs is confined mostly to the large eastern cities, where they are consumed chiefly in high-class hotels, restaurants, and clubs. This specialty in sheep production should be undertaken only by experts who have nearby markets that will pay the high prices such products must command.[57]

The demand for hot-house lambs comes from December, or even earlier, up to Easter, the prices usually being best early in this season. Hot-house lambs must be fat, for the condition of the carcass is more important than its size. Lambs that are not well finished or that have poor conformation bring unsatisfactory prices. The lambs must therefore be forced ahead rapidly by feeding them a suitable concentrate mixture in a creep. Thus fed, they should be fat at 40 to 60 lbs. live weight. The lambs are dressed on the farm, according to the demands of the market to which they are to be shipped.

For the production of hot-house lambs, the ewes must be bred in the spring, instead of at the usual season in the fall. The ewes best suited for this purpose are purebreds, grades, or crossbreds of the Dorset, Merino, or Rambouillet breeds, for the other breeds will not usually breed at the right season. Crossbred Dorset-Merino ewes are excellent, when bred to a good mutton ram.

The ewes should have abundant pasture during the summer and fall, so they will be in condition to provide a good milk flow. After lambing, the ewes should be fed liberally on a good concentrate mixture and legume hay, with silage in addition, if available. As has been pointed out, the lambs should receive additional feed in a creep, so they will be ready for market as soon as possible.

1321. Cost of keeping ewes; net returns.—The cost of maintaining ewes will vary widely in different parts of the country. The expense will be reduced considerably when the flock can get an important part of the fall and winter feed by grazing on stalk and stubble fields, thus utilizing feed that might otherwise be wasted.

Where no such grazing is available, it will require 400 to 600 lbs. or more of hay or other dry roughages (after deducting the amount wasted) to carry a breeding ewe of average size, weighing 100 to 150 lbs., through the winter period of 5 to 6 months. Also, for the best results about 20 lbs. of concentrates per ewe should be fed prior to lambing and perhaps additional concentrates for flushing the ewes at the breeding season. In the case of ewes lambing early, additional concentrates will be needed for the ewes and lambs before the pasture season.

In addition to the cost of winter feed and of pasture, in estimating the total cost of keeping ewes there must be included the man and the truck or horse labor, the interest, depreciation, and mortality risk on the ewes, the housing charge, and any miscellaneous expenses. On the credit side are the wool and lambs produced and the value of the manure.

The excellent net returns that can be secured from a well-fed and properly managed flock of ewes are shown by the record of a flock of 42 to 88 western ewes over a period of 7 years, 1946 to 1952, at the Spooner Branch Station in Wisconsin.[58] This station is located on very sandy land, but has been brought to good fertility by fertilization and careful management. The ewes were bred to purebred mutton rams.

Over the 7 years, the average percentage of lambs raised was 151 per cent, and the average weight of fleeces from the ewes was 9.7 lbs. The average net labor return per ewe was $22.89, after deducting all expenses for feed, veterinary services and medicine, shear-

ing, ram cost, death losses, and marketing wool and lambs.

In a 10-year study on farms in southeastern Minnesota, it was found that average amounts of feed consumed annually per head of mature sheep, in addition to pasture, were 60 lbs. concentrates, 144 lbs. tame hay, 87 lbs. wild hay and corn fodder, and 130 lbs. silage.[59] In these flocks, which contained an average of 36 head of mature sheep equivalent, the percentage lamb crop was 96 per cent; the average wool yield, 7.0 lbs.; and the annual death loss 9 per cent. The total value of lambs and wool was a little more than twice as great as the total feed cost.

The average amounts of feed required yearly per head in 103 flocks in western New York, containing an average of 58 sheep, were 46 lbs. of concentrates, 486 lbs. of hay, and 190 lbs. of other roughage, including silage, fodder, and stover.[60] On the average, 7.8 lbs. of wool were sold per head, 97 lambs were raised per 100 ewes, and 6.1 hours of man labor were required a year per sheep. The cost of feed, including pasture, was 58 per cent of the total gross cost, before allowing a credit for the value of the manure.

In Pennsylvania tests purebred Shropshire ewes averaging 172 lbs. in weight required an average of 2.5 lbs. legume hay, 3.1 lbs. corn silage, and 0.2 lb. concentrates per head daily in winter.[61] An average of 85 lbs. of bedding was needed per ewe during the winter and 735 lbs. of manure were produced per ewe. The ewes sheared an average of 7.66 lbs. and the average weight of the lambs at weaning was 59 lbs. Delaine-Merino ewes required somewhat less feed because of their smaller size and sheared 11.1 lbs. Their lambs averaged 53 lbs. at weaning.

1322. Factors affecting the net income from sheep.—The various cost-accounting studies that have been made of sheep and wool production show clearly that some of the most important factors affecting the net income are the following: (1) A flock of sufficient size to make possible the efficient use of labor, buildings, equipment, and ram. (2) A flock that has been selected to produce a high yield of wool per ewe and a high percentage of lambs as well. (3) Proper feed and care of the ewes, so that they will produce vigorous lambs and furnish plenty of milk for them. (4) Plenty of good pasture, preferably rotated so as to aid in the control of parasites. (5) Thorough control of stomach worms and other internal parasites, and also control of ticks and lice.

1323. Internal parasites.—In all humid regions stomach worms and other internal parasites may seriously reduce the income from sheep unless damage from these parasites is prevented. Severe infection with internal parasites retards growth, prevents fattening, reduces the wool yield, lowers the resistance to other diseases, and may cause heavy death loss. Lambs are usually affected more seriously than older sheep.

The eggs of the stomach worms pass out in the droppings of the sheep and are scattered about the pasture, where they soon hatch and develop to the larval stage. Sheep become infected only by swallowing the worms at this stage.

Fields on which no sheep or goats have grazed for a year, and those that have been plowed and cultivated since they were grazed, are practically free from infestation. Where the winters are cold, the parasites on a pasture will be largely killed during the winter, if there are no sheep on it. Also, keeping sheep off a field for 3 months in summer will greatly reduce the infestation with parasites. During warm weather, clean pastures may become infested in 10 to 20 days of grazing.

To prevent serious trouble from internal parasites, medicinal treatment should be combined with proper feeding and good pasture management. Thrifty, well-fed sheep are much better able to resist parasites than those that are rundown. If the flock could be moved to fresh uncontaminated pasture every 2 to 3 weeks during the grazing season, there would generally be little trouble from internal parasites. However, this is not practicable on most farms. It is therefore

necessary to rely largely on medicinal treatment for parasite control.

The best methods for preventing trouble from internal parasites will depend on the climatic conditions in any region. Specific advice should therefore be secured from a local veterinarian who has had experience with sheep diseases, or from the state agricultural college or county agricultural agent.

The use of phenothiazine is largely displacing the older vermifuges for the control of internal parasites in sheep, because it is effective against more kinds of parasites than any other vermifuge. In some humid regions the following is an effective plan of control: Drench the sheep with phenothiazine in late fall or early winter, after they come to the barn. Drench them again with phenothiazine before they go to pasture in the spring. Ewes should not be drenched within 2 months of lambing. During the grazing season give the sheep access to a mixture of 1 lb. of phenothiazine and 9 lbs. of coarse salt, and provide no other salt.

When this system is combined with good pasture management and with as much rotation of grazing as is practicable, it may provide good control without other treatment. Often, however, it is necessary to drench the sheep at monthly intervals during the grazing season with the combined copper sulfate-nicotine sulfate solution. This eradicates certain worms, especially tapeworms, which are not controlled by phenothiazine. Feed and water should be withheld for 10 to 15 hours before sheep are drenched with this solution, and for 4 to 6 hours afterwards. Withholding feed and water is not necessary when sheep are drenched with phenothiazine.

1324. External parasites.—To eradicate ticks or lice, both mature sheep and lambs should be dipped with a suitable preparation in the spring as soon as the cuts have healed on the sheep that have been shorn. If badly infested, the sheep should be dipped a second time to kill any parasites that were in the egg state before. A second treatment is not needed if a dip is used which leaves an effective residue in the fleece for a sufficiently long time. A second dipping should be 24 to 28 days later for ticks and 14 to 16 days later for lice. The sheep should be dipped on a clear, warm morning, so that they will dry during the day. In fall the flock should be dipped again, if necessary.

Power dusters have recently been developed for applying a suitable insecticide in dust form to eradicate ticks and lice. This method is especially advantageous in cold weather when dipping is injurious.

In case of sheep scab, prompt and thorough dipping with an effective preparation is necessary.

1325. Range sheep production.—The great numbers of sheep in our western states are mostly kept under range conditions.[62] The ranges grazed by sheep are usually the rougher areas of the plains, foothills, and mountains.

The high mountain ranges furnish excellent grazing for sheep during the summer months, for there is usually an abundance of water and good pasturage, and the days are cool. The plains and the semi-desert ranges, which are too hot and dry in summer, furnish winter range, and during the spring and fall the foothills are used to good advantage. Sheep do well on sagebrush and salt-sage browse, neither of which is palatable to cattle, and cattle can browse on the higher growing species which sheep cannot reach. For grazing throughout the year, 4 to 20 acres of range are commonly needed for a mature sheep.

The unit, or band, of range sheep may vary considerably in size, but it usually contains 2,000 to 2,500 sheep. From lambing time to weaning, 1,000 to 1,500 ewes and their lambs are usually kept in one band, and after the lambs are weaned, two bands of ewes may be combined for the breeding and winter period. During lambing, a smaller number of ewes is run together.

Most of the western sheep producers use the same general method in handling their sheep. A band is put in charge of one herder, who, with his dogs, stays with the sheep, day and night,

throughout the season. The herder is quartered in a covered wagon, equipped for his needs, except when he is near headquarters or in summer when the sheep are on a high mountain range where the wagon cannot follow. A tent is then used for shelter.

A camp tender, with a wagon or pack animals, supplies the herder with food and moves his camp, as the sheep need new grazing ground. One camp tender may take care of two or more herders, and in large enterprises a range foreman is usually in charge of several bands. Additional help is needed during lambing and shearing. In Texas, a common method is to keep the range sheep in fenced pastures, where they can graze undisturbed. Under this system one man can care for a larger number of sheep, and the sheep can make better utilization of the feed than on an unfenced range.

On the ranges the sheep receive no feed except the pasturage during the growing season, and often a range at low altitude furnishes most of the winter feed, especially in the southern districts. Usually, however, it is necessary to make provision for additional feed during winter, such as alfalfa and other hay, or cottonseed cake or meal. The feeding of supplements to ewes wintered on the range has been discussed previously in this chapter. (**1309**)

Where early lambs are produced, as in certain valleys of California, Oregon, and Arizona, the ewes lamb in sheds from late January to early March. The lambs are raised on the valley and foothill ranges and are marketed as fat "spring lambs" in spring or early in summer, before the low-lying ranges dry up. In this system aged ewes are frequently used, which would not thrive under the usual range system.

The more general range practice is to have the ewes drop their lambs on the range, usually in May. After the ewes are sheared, the bands are gradually moved to the high mountain ranges where they graze during the summer. The wether lambs and also the ewe lambs which are not needed for replacements in the ewe flocks are marketed in the fall, generally in September and October. A large proportion of the lambs may be fat enough for immediate slaughter, if the summer forage has been abundant. The rest are fattened for market by men who make this a speciality.

II. Fattening Lambs and Sheep

1326. Fattening feeder lambs.—Considerable numbers of the lambs raised on the western ranges are not fat enough for slaughter at the time they are marketed. They are therefore sold as feeders and then fattened in districts where grain and other concentrates are cheaper than in the range area. Also, many farm-raised lambs are not fat enough for sale at the end of the pasture season. These are fattened during late fall and winter.

The juiciness and flavor of lamb meat are greatly improved by proper fattening. Texas experiments indicate, however, that the tenderness of lamb is not increased by fattening.[63]

At one time most of the western lambs were fattened by large operators who each fed thousands of lambs a year. Now, most of the lambs are fattened by farmers, who finish one or more carloads. They raise most of their own feed and usually consider that enough fertility is returned to their land through the feed lot to pay the labor cost of feeding.

Just as is the case in fattening feeder steers, good judgment in purchasing the feeder animals and in selling them at the right time are exceedingly important in determining whether there will be a profit or a loss in the feeding operations. The cost of the feeder lambs forms more than half the cost of the fattened animals. Also, the cost per 100 lbs. of the gains made in the feed lot is usually greater than the selling price per 100 lbs. of the lambs when fat. Therefore, to make a profit the fat lambs must sell at a higher price per hundredweight than their cost as feeders. In other words, a margin is required between the initial cost and the selling price. (**1188**)

Sometimes lambs are fattened under

a "contract" system. The farmer-feeder does not buy the lambs, but furnishes the feeds and fattens the lambs under a definite contract with the producer. Often a specified price per pound is paid for the gains made.

In fattening lambs it must be borne in mind at all times that the object is to convert a thin animal into a finished product—a lamb fat enough to meet the market demands. Each year many farmers lose money because they dump half-fattened lambs on the market, where they again are sold as feeders, to be finished for the market by someone else, who is better acquainted with the market demands.

Usually men who feed lambs only occasionally make less of a financial success of the undertaking than those who feed each year. The latter may lose money in the unprofitable years, but this will be offset by good returns the rest of the time. Just as important, they gain experience in this business, where good judgment is of great value.

1327. Types of lamb fattening.—Large numbers of lambs are fattened in the vicinity of the western beet-sugar factories, where the beet by-products—beet pulp, beet tops, and molasses—are fed, along with alfalfa hay and usually some grain in addition. In these districts and in general west of the Missouri River, most of the lambs are fed in open yards, with no shelter except a wind break. (1289)

The hay is usually fed in lanes which extend between 2 rows of feed lots, each of which accommodates 400 to 500 lambs. The low fences bordering the lanes have a 7- or 8-inch space between the first and second boards, through which the lambs feed on the hay. The hay from stacks is hauled down the lanes and piled along the fences, being pushed up to them 2 or 3 times a day as it is eaten away. Sometimes racks are used for the hay, or chopped hay is fed in self-feeders. The grain is fed in flat-bottomed troughs.

In the corn belt many farmers fatten western lambs in late fall and winter on harvested feeds, sheltering them in a barn or an open shed, with or without an exercise lot. Usually, all or nearly all the feed is raised on the farm, with the exception of protein supplements. Fattening lambs chiefly on pasture in the fall, and fattening them in corn fields are other methods used. (**1336, 700**) Often lambs are grazed on stubble fields or on aftermath in meadows and then finished in a dry lot. In the southern plains states, lambs are often fattened chiefly by grazing them on fields of winter wheat. Many lambs are also fattened largely on pea-vine silage in the vicinities of pea canneries, especially in Wisconsin.

In Michigan and eastward, the lambs are generally not turned out from the barn or shed for exercise. Commonly, the lambs are brought to full feed as quickly as possible and then are given all the grain they will clean up. Often they are self-fed, as is discussed later. (1335)

Several large feeding yards are located near some of the large markets, on the main railroads from the West. Here, lambs which have been fattened in the western states are often fed and rested for a few days, so they will reach the market in good condition and without heavy shrinkage. Also, lambs may be carried through the entire fattening period at such yards.

Some men usually fatten two lots of lambs each season, marketing the first in early winter and the second late in the spring. Should the weather grow warm before the lambs are finished, they are often shorn so they will make better gains. (**1293**)

Others, who market their lambs in the spring, when prices are usually higher than in the winter, use a deferred system of fattening. They buy small lambs in the fall, when it is easier to get thrifty feeders than it is in winter. Then they feed them on only hay or other roughage until 60 to 80 days before the time they are to be marketed, when grain feeding is started and the lambs are finished on a liberal feed of grain. During the preliminary period on roughage alone, the lambs make very little gain, but the total cost of fattening will

usually be less than if a half allowance of grain is fed during the entire time.[64]

This method utilizes a large proportion of roughage and requires a minimum amount of concentrates.[65] Unless grain is high in price in comparison with roughage, the cost of the gains is apt to be greater in the deferred system of fattening than when grain is fed from the beginning of the fattening period.

1328. Selecting feeder lambs.—The most desirable feeder lambs are thrifty, broad, compact, and relatively low-set, and have smooth skin free from wrinkles when fattened. Such lambs yield the best carcasses and thus bring the highest price per hundredweight. Feeder lambs of this type naturally cost more per 100 lbs. than those of lower grades, and therefore do not always yield the greatest net return from fattening.

Thrifty lambs that lack some of the desirable qualities may make nearly as rapid and economical gains as do feeder lambs of the best grade, but generally sell at a lower price when fattened. Good judgment is consequently needed in deciding what grade or type of lambs to purchase.

Most of the feeder lambs from the northern range states weigh 75 to 85 lbs. when loaded in the West. On receipt at eastern feed lots, the lambs usually weigh 65 to 75 lbs. The lambs from the southwestern ranges are usually somewhat lighter.

During a fattening period of 80 to 120 days lambs should gain 25 to 30 lbs. per head, which brings them to the size desired by the market. The demand is generally best for well-fattened lambs weighing 95 to 100 lbs., and fat lambs heavier than 105 to 110 lbs. often sell at a discount.

Light-weight lambs commonly require a longer fattening period than do heavier lambs to reach the same degree of fatness, but there may be little difference in the amounts of feed required per 100 lbs. gain.[66]

Some men specialize in fattening light-weight lambs, or "peewees," sorted out from the shipments of feeder lambs from the ranges. These can usually be bought at a considerably lower price than the larger ones. Though some of these "peewees" are apt to be unthrifty, most of them are merely younger than the rest or are small because their mothers were poor milkers.

If they are thrifty, such lambs, usually weighing 50 lbs. or less, will make nearly as rapid gains as larger ones and their gains will generally be cheaper, because of their younger age.[67] Naturally, such lambs require a longer feeding period to reach a certain market weight or degree of fatness, and good shelter and more care are necessary in feeding them. Also, they should be fed apart from larger and stronger lambs.

Feeder lambs produced in the humid districts are more apt to be infected with stomach worms and other parasites than are western feeder lambs, especially those from the northern ranges, and therefore often make less rapid and more expensive gains. However, if the lambs are thrifty and are thoroughly drenched before being placed on feed, they may make as good gains as western lambs.[68] The purchase and fattening of cull native lambs should be undertaken only by an expert, as the undertaking may be hazardous because of heavy death losses.

There is not enough difference in the gains made by ewe lambs and by wether lambs in the feed lot, or in the market value when fat, to cause any decided preference among experienced men. However, wether lambs usually make slightly more rapid gains than do ewe lambs.[69]

Fine-wool lambs are apt to make less rapid and less economical gains than do lambs having considerable mutton blood. Smooth-bodied Rambouillet lambs generally make larger gains than wrinkly, fine boned lambs of fine-wool breeding, and yield much better carcasses.[70]

1329. Gains made by fattening lambs; feed per 100 lbs. gain.—The amounts of feed consumed per head daily by fattening lambs and the feed requirements per 100 lbs. gain are shown by the following summary, compiled by the author, of the results of many experi-

ments in which a ration of corn grain and alfalfa or clover hay has been fed. This ration is excellent and may be taken as a standard with which other rations are compared.

There are given first in the table the average results from experiments in which 44 lots, including a total of 1,171 lambs, were fed for periods averaging 80 days on a liberal allowance of shelled corn (1.1 lbs. a head daily or more, on the average) with alfalfa or clover hay for roughage. The results are also presented for 43 experiments in which a total of 2,300 lambs were fed for an average of 97 days on a limited allowance of shelled corn (an average of less than 1.1 lbs. a head daily) and all the alfalfa or clover hay they would eat.

and their weights in the feed lot at the end of the experiment. Under commercial conditions, the amount of gain is usually considered to be the difference between the initial purchase weight, before shrinkage in shipment to the farm, and the final shrunk weight at the market.

1330. Results in commercial lamb fattening.—The results secured by farmers in the commercial fattening of lambs are shown by studies during 5 years, 1931–35, on Michigan farms where a total of about 130,500 lambs, chiefly western, were fattened.[71] On the average, 796 lambs were fattened each year per farm. The lambs averaged 63 lbs. in weight at the start and were fed for an average of 110 days. During this period,

Fattening lambs on an excellent ration

Average ration	Initial weight Lbs.	Daily gain Lbs.	Feed for 100 lbs. gain Corn Lbs.	Feed for 100 lbs. gain Hay Lbs.
Corn allowance liberal				
Shelled corn, 1.3 lbs. Alfalfa or clover hay, 1.4 lbs.	63	0.34	387	418
Corn allowance limited				
Shelled corn, 0.9 lb. Alfalfa or clover hay, 2.3 lbs.	62	0.31	305	727

The lambs fed the liberal allowance of corn ate 1.3 lbs. corn and 1.4 lbs. alfalfa hay and gained 0.34 lb. per head daily. For each 100 lbs. gain in weight they consumed 387 lbs. corn and 418 lbs. hay. The lambs fed the limited allowance of corn, with all the legume hay they would eat, gained only a little less rapidly (0.31 lb. per head daily), because of the good quality of the hay fed in the experiments. For each 100 lbs. of gain these lambs required 305 lbs. corn and 727 lbs. hay.

It should be borne in mind that in these experiments thrifty lambs were fed on feeds of good quality by experts. Also, the gain reported in feeding experiments differs from that secured in commercial feeding operations. In a feeding experiment the gain is the difference between the initial weights of the lambs in the feed lot when the experiment is started

the average gain per lamb, or the difference between the purchase weight at the market and the sale weight at the market plus the weight of wool shorn from some of the lambs, was 26 lbs., or 0.24 lb. per head daily. In similar Colorado studies of lamb-feeding results over a 22-year period, the average daily gain was 0.19 lb. for an average feeding period of 145 days.[72]

On the Michigan farms 620 lbs. of grain and other concentrates and 550 lbs. of hay and other roughage were required per 100 lbs. of net gain in weight, based on market weights and deducting the initial weights of the lambs that died. The lambs were fed an average of 1.3 lbs. grain and other concentrates and 1.1 lbs. hay and other roughage per head daily. The total average amounts of feed used per finished lamb were: corn, 62 lbs.; oats, 14 lbs.; grain screenings and

salvage grains, 35 lbs.; other concentrates, 30 lbs.; hay, 88 lbs.; and other roughage, 37 lbs.

The cost of feed and labor amounted to 95 per cent of the net on-the-farm expenses, after credit was allowed for the value of the manure.

1331. Rations for fattening lambs.—To secure rapid and economical gains, lambs must be fed a well-balanced ration with a liberal amount of grain or other concentrates, and also plenty of good roughage. Many different rations are satisfactory. Several example rations, which are adapted to conditions in various regions, are given in Appendix Table VII.

As has already been emphasized, a ration of corn or other grain and plenty of good alfalfa or other legume hay is excellent for fattening lambs. (1329) Information is given in Chapters XX and XXI concerning the relative values of the different grains for lamb feeding, and in Chapter XVI concerning the values of the various kinds of legume hay. Other carbohydrate-rich feeds, such as dried beet pulp, wet beet pulp, cane or beet molasses, and hominy feed, can be used to replace all or part of the grain for fattening lambs. These and other feeds are discussed in the respective chapters of Part II.

It has been shown in the preceding chapter that if an abundance of good legume hay is fed with corn grain, it is doubtful if it will ordinarily pay to add a protein supplement to the ration. (1270) When barley, oats, or wheat is fed instead of corn, there is still less benefit from adding a protein supplement.

Corn silage or sorghum silage is excellent as part of the roughage for fattening lambs and has a high value per ton when thus fed. Because such silage is much lower than legume hay in protein, it usually pays well to add a protein supplement to a ration of grain, such silage, and legume hay. (1271)

Corn silage or sorghum silage can even be used as the only roughage for fattening lambs, if care is taken to feed the proper amount of protein supplement and also of ground limestone or some other calcium supplement. (1278) The gains are generally more rapid, however, when hay is fed in addition to silage. Also, the silage has a higher value per ton when thus used than when it is fed as the only roughage.

In 3 New York experiments lambs fattened on a ration of shelled corn, protein supplement, alfalfa hay, and corn silage gained 0.40 lb. per head daily.[73] Others fed corn silage as the only roughage with shelled corn, protein supplement, and ground limestone, gained 0.36 lb. daily. In these experiments corn silage was worth 56 per cent as much per ton as alfalfa hay when fed in combination with hay, but only 37 per cent as much as alfalfa hay when used as the only roughage.

STOVER NOT A GOOD ROUGHAGE

Corn stover is too low in nutrients to be a satisfactory roughage for fattening lambs.

When lambs are fed both corn or sorghum silage and legume hay, they are generally allowed to eat as much of each as they will clean up satisfactorily. However, the advantage from feeding legume hay in addition to the silage can be gained when only a small amount of legume hay is fed.

In New York experiments lambs made slightly more rapid gains when fed only one-quarter pound of alfalfa hay, with silage and corn grain full-fed and with sufficient protein supplement to balance the ration, than did others fed more hay.[74] Of course, more protein sup-

plement was needed to balance the ration that had the very small amount of alfalfa hay.

Mixed hay of good quality and containing a considerable proportion of legumes is a satisfactory substitute for legume hay in feeding fattening lambs. For lambs, grass hay should be early cut and well cured. Otherwise, it is much inferior to legume hay. Information is given in the respective chapters of Part II concerning various kinds of grass hay and also other roughages that can be used for fattening lambs, including corn fodder, sorghum fodder, bean pods or bean straw, sugar beet tops, and cottonseed hulls.

1332. Getting the lambs on feed.—Lambs that are not used to grain or silage must be accustomed to these feeds gradually, or scouring and other digestive troubles will result, and perhaps even heavy death losses. When feeder lambs are received on the farm, they should be given only a feed of hay for their first meal, and this should be preferably mixed hay or grass hay, as pure legume hay may be too laxative for this first feed. It is risky to turn onto abundant pasture hungry feeder lambs that have just arrived, as this may cause bloating or scours.

After the lambs have rested from shipment, they may be fed as much hay or other dry roughage as they will clean up, but only a small amount of grain (not over 0.1 to 0.2 lb. per head daily) should be fed at first and only a little silage. The grain should be sprinkled along the trough, so no lamb can get too much. The allowance of grain should be increased gradually, until in 4 to 5 weeks the lambs are receiving 1.0 to 1.25 lbs. of grain per head daily. During this time no more grain should be fed than will be cleaned up in about 15 minutes. If silage is fed, the amount should also be increased gradually, until the lambs are getting all the silage they will eat twice a day.

If it is desired to fatten the lambs as rapidly as possible by feeding them all the grain they will eat, further increases should be made cautiously, and only if all the lambs are cleaning up their feed regularly. Example rations for fattening lambs when on full feed are given in Appendix Table VII.

In no case should the getting of the lambs on feed be hurried, for this is apt to cause serious digestive trouble. It is wise to start the lambs on a mixture consisting chiefly of a bulky feed, like oats or wheat bran. The proportion of corn or other heavy feed is then gradually increased. When the lambs are on full feed, corn is very often fed as the only concentrate, with a small amount of protein supplement, if this is needed to balance the ration. On warm days in winter it is often necessary to reduce the grain allowance slightly, or the lambs may go off feed.

Sheep feeders do not begin operations at an early hour in winter, preferring not to disturb the animals until after daybreak. The lambs are usually fed twice a day, grain being given first, followed by silage, if this is used, with the hay last. Fattening lambs may gain a trifle faster when fed grain more often than twice a day, but it is doubtful whether this is worth the additional labor.[75]

Plenty of salt and fresh water should always be provided. The troughs in which grain is fed should be kept clean, and there should be ample space, so that each lamb can get its share of grain. If any evidence of lice, ticks, or scab is found, the lambs should be dipped thoroughly before they are put on feed. When necessary, they should be drenched to eradicate stomach worms, but this is not usually needed in the case of western range lambs.

Regularity and quiet are of especial importance to secure good results in fattening lambs.

1333. Amounts and proportions of concentrates and roughage.—Experiments have shown clearly that under conditions throughout the corn belt and the eastern states, it is usually most profitable to give fattening lambs a liberal allowance of grain after they have been

brought onto feed, except when it is desired to fatten them slowly for a later market.[76] If lambs are fed about as much grain as they will clean up twice a day, in addition to what good hay or other roughage they will eat, they will make rapid gains at a reasonable cost, reach a good market finish, and sell at a higher price than if less thoroughly fattened.

It is very important to feed fattening lambs plenty of good roughage.[77] Experiments have shown that if the ration, on the air-dry basis, has more than about 50 per cent of corn or other heavy grain, the danger of death losses from overeating disease is increased. Also, even when this does not occur, the feed cost per 100 lbs. gain is apt to be higher, when too large a proportion of grain is fed.

Kansas experiments have shown that lambs utilize the nutrients in their feed more efficiently when there is a proper balance between concentrates and roughage.[78]

If one wishes to fatten heavy lambs as rapidly as possible, so that they get fat before they get too heavy, it may be desirable to increase gradually the proportion of corn or similar grain in a self-fed mixture up to 60 per cent.[79] The rest of the mixture should be good-quality ground legume hay, with protein supplement as needed. When such a mixture is fed, it is advisable that the lambs be vaccinated against overeating disease, as stated in the next article.

In the West, where hay is usually cheap in comparison with grain, the allowance of grain is often restricted somewhat. However, if the lambs are to be sold on a market that pays a satisfactory premium for well-fattened animals, it will generally pay to feed 1.0 lb. or more of grain per head daily.[80] Lambs will not reach a satisfactory degree of fatness unless fed at least about 0.75 lb. of grain or other concentrates per head daily, after they have been brought on feed. On hay alone or even on hay and good corn silage, they will usually gain only 0.03 to 0.17 lb. per head daily and will grow rather than fatten.[81]

If it is desired to limit severely the amount of grain fed fattening lambs, it is best during the first half of the fattening period to feed them only hay or hay and silage, or else only a very small amount of grain, and then to finish them on a full feed of grain. This produces more rapid and cheaper gains than feeding half the usual amount of grain throughout the fattening period.[82]

1334. Death losses; enterotoxemia, or overeating disease.—Some death losses are unavoidable in the commercial fattening of lambs. However, the mortality should not exceed 3 to 4 per cent when healthy lambs are fed by experienced men. Much higher losses often occur if the lambs are not thrifty or if they are fed carelessly.

Enterotoxemia, or so-called "overeating disease," is generally the cause of most of the death losses in fattening lambs. This usually occurs only in lambs which have been on full feed for some time and which are being crowded on a heavy allowance of grain, so they will make rapid gains. The lambs affected are almost always the largest, fattest, most vigorous and greediest in the lot.

Sometimes the disease causes very sudden death, the lamb throwing back its head, staggering, falling to the ground, and dying in convulsions, as though from an apoplectic stroke. More commonly, the lambs live a few hours, showing typical brain symptoms, such as the head being thrown back or the lamb running in a circle or pushing against a fence. In many instances, lambs which have appeared thrifty the previous day are merely found dead in the morning. In only a few cases do the lambs recover.

Studies have shown that the disease is caused by a severe digestive disturbance in which bacteria called *Clostridium perfringens* produce toxins, or poisonous substances.[83] These dangerous toxins are absorbed from the digestive tract.

When deaths from the disease are occurring in a lot of fattening lambs, they can be stopped practically overnight by

withholding the grain. However, it is generally necessary to feed grain rather liberally to fattening lambs, or they will grow too large before they get fat enough to meet market demands.

To reduce the losses as much as possible when lambs are fattened rapidly, the following precautions must be observed. The utmost care must be taken to get the lambs on feed without producing digestive disturbances. All possible measures should be taken to prevent gorging. The grain must be distributed in the troughs so no lamb can get more than its share.

If lambs are self-fed, the grain should be mixed with sufficient bulky feed, preferably ground or chopped hay, to prevent digestive trouble. Even when lambs are hand-fed, it is wise to mix the grain with ground or chopped hay if they are being crowded on all the grain they will eat. When lambs are fed a mixture of grain and hay, it is best to let them also have as much long hay or silage as they care for.

Where a considerable number of lambs are being fattened, it is a good plan to sort out the fattest lambs as soon as they are well finished, and market them. If this is done, the amount of grain must be reduced and it must be remembered that the lambs which were ready first were the heartiest eaters.

Vaccination of feeder lambs with a bacterin largely prevents enterotoxemia during fattening. An anti-toxin, which is also made commercially, is also used on animals already affected with the disease.

Adding to the ration either flowers of sulfur or sodium bicarbonate (baking soda) has been recommended as a preventive of enterotoxemia.[84] However, often neither of these additions is effective in preventing the disease. In some tests an antibiotic supplement has reduced the occurrence of enterotoxemia. (1283)

1335. **Self-feeding.**—Often the men who fatten large numbers of western lambs use self-feeders to save labor. Self-feeding usually produces more rapid gains than hand-feeding, but it frequently results in greater death losses from overeating disease. Self-fed lambs generally require more grain and less hay per 100 lbs. gain than hand-fed lambs, and hence utilize less farm-grown roughage.

The safest method of self-feeding lambs is to feed, throughout the fattening period, a mixture of grain and some very bulky feed, especially ground or chopped alfalfa hay, or other good hay. It is best to grind the grain, so that it can be mixed more uniformly with the other feed, and so that it will not separate out of the mixture.

When the lambs are first started on grain, such a mixture as only 100 lbs. of grain with 300 lbs. of ground hay may be fed. The proportion of grain is then gradually increased until after 3 or 4 weeks a mixture of equal weights of grain and hay may be fed. Feeding a larger proportion of corn or other heavy grain is not desirable, for it may not increase the gains and it increases the danger of overeating disease.[85]

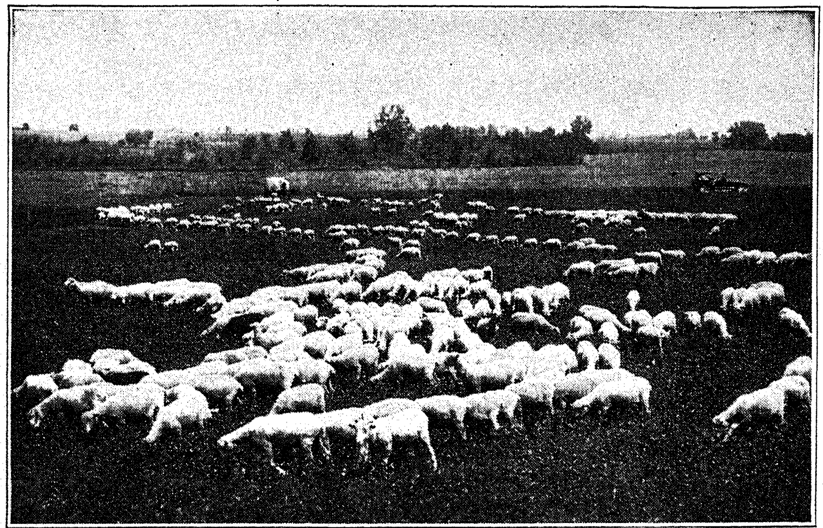
The self-feeders must be given proper attention, so they do not become clogged. When a suitable mixture is self-fed and the lambs have feed available at all times, so they do not get very hungry and then eat too much, the death losses may be no greater than in skillful hand-feeding.

The results from self-feeding a mixture of grain and ground or chopped hay are shown by 12 experiments in which a mixture of corn and alfalfa hay was self fed in comparison with hand-feeding corn and alfalfa hay separately.[86] The self-fed lambs ate an average of 1.4 lbs. corn and 1.5 lbs. hay and gained 0.37 lb. per head daily. The hand-fed lambs ate 1.2 lbs. corn and 1.5 lbs. hay and gained 0.34 lb. on the average. For each 100 lbs. gain the self-fed lambs required 372 lbs. corn and 406 lbs. hay, while the hand-fed lambs required 353 lbs. corn and 456 lbs. hay. In these experiments the feed cost of 100 lbs. gain at usual feed prices was fully as cheap for the self-fed lambs. Often, however, the gains are somewhat more expensive when lambs are self-fed.[87]

The use of chaffy grain screenings in place of ground or chopped hay in self-feeding lambs is advisable only if such low-grade material can be secured very cheaply. In New York tests such screenings were not worth their cost.[88] In Michigan trials oat hulls were worth about one-half as much as ground alfalfa hay, when used as the bulky feed for self-feeding lambs.[89] In Wyoming experiments, mixing dried beet pulp with the grain did not prevent death losses as well as did the use of ground alfalfa hay in the mixture.[90]

The danger from self-feeding is greatest when a heavy concentrate, like corn or barley, is fed alone in a self-feeder. Even when the lambs are brought on feed by careful hand-feeding and only then turned to self-feeders filled with such grain, heavy losses may occur.[91] There is less danger when the lambs, after being brought on feed by hand-feeding, are first self-fed such a bulky mixture as 3 parts oats and 1 part corn, and then are gradually changed to corn alone or corn and supplement.[92] However, sometimes heavy death losses occur even after lambs have been self-fed for several weeks on corn or other heavy feeds alone, with hay fed separately.

Lambs cannot be trusted to balance their ration if they are self-fed separately corn or other grain and a protein supplement like linseed meal or cottonseed meal. Sometimes they will eat about the proper amount of the supplement, but at other times they will take much more than is needed.[93] The supplement should therefore be mixed with the grain in the proper proportion.



A Band of Western Lambs Fattening in the Corn Belt

Many corn belt farmers make a practice of fattening one or more carloads of western lambs in the fall on aftermath, stubblefields, or standing corn.

1336. Fattening lambs on pasture in the fall.—Fattening lambs chiefly on pasture in the fall and then finishing them in dry lot, is a common practice with farmers who raise their own lambs and with many who buy western feeder lambs. Until cold weather sets in, the lambs may be grazed on stubble fields, aftermath in meadows, or rape or other pasture, with or without grain in addition. Rape is often seeded in small grain to increase the fall feed for lambs, the seeding not taking place until the small grain is well above ground, lest the rape grow so large as to reduce the yield of the grain crops.

Thrifty lambs placed on feed in the fall should be ready for sale in December or early in January. There is then usually a scarcity of good lambs on the market, since the grass-fat lambs have been marketed and those in winter feed lots are not yet finished.

Many lambs are fattened during the fall and winter on winter wheat [94] pasture in Kansas, Oklahoma, and other states. (583) Lambs will reach a good market finish on wheat pasture alone, if there is plenty of forage and the weather is suitable. There should always be a reserve supply of harvested feed on hand to carry the lambs over periods of bad weather, or for use if the wheat pasture becomes scanty before the lambs are fat.

In order to avoid digestive disturbances, one should be sure that the lambs are well filled with dry roughage before they are first turned on wheat pasture. Also, it may be a good plan to let them have access to some dry feed, such as sorghum stover, straw, or sorghum stubble, while they are on the wheat field. This reduces digestive trouble and helps prevent wheat poisoning. (179)

In the South fattening lambs make excellent gains on such winter pasture as ryegrass, rye, or oats, without grain feeding.[95] In the Imperial Valley of California lambs reached satisfactory finish, without grain feeding, on alfalfa pasture in which barley had been seeded in the fall to furnish additional winter feed.[96] Because of dog danger, the lambs were kept in a dog-proof corral at night and fed alfalfa hay.

Fattening lambs on standing corn has been discussed in a previous chapter. (700)

1337. Shrinkage in shipment; dressing percentage.—Fat lambs usually shrink 4 to 7 per cent in weight when shipped less than 150 miles to market. If they are shipped greater distances, the shrinkage may be as high as 8 to 10 per cent or more.

There is generally no need to make any decided change in the ration fed fattening lambs before shipment. It may be advisable to reduce the amount of grain somewhat the day before shipment, but the lambs may be allowed the usual amount of roughage. Oats are an excellent feed for sheep in transit, as they are bulky and not laxative. When sheep are marketed off pasture, especially rape pasture, shrinkage from scouring may be avoided by giving them hay or other dry feed for a day or two before shipment.

Based on market weights, fat lambs usually yield 47 to 51 per cent of dressed carcass. Exceedingly fat lambs or sheep may dress 60 per cent or even more, but such fat carcasses are very wasteful.

III.—Milk Goats; Angora Goats

1338. Milk goats.—Milk goats are of considerable importance in continental Europe, many families, especially of the poorer classes, relying on goats for their daily supply of milk. Much goats' milk is also used in Europe for the manufacture of certain types of cheese. Though milk goats have never become important in the United States, there are limited numbers in many states, the greatest number being in California. They are especially well suited for furnishing the milk supply for families living in small towns and the suburbs of large cities, or on fruit and truck farms where there is not enough feed available for a cow. A milk doe can often secure much of her feed from garden and kitchen waste or lawn clippings, or by grazing in such areas as vacant lots and rocky hillsides.

The milk of most breeds of milk goats averages 4.0 per cent or more in fat.[97] The fat globules are much smaller in size than those of cows' milk, and goats' milk forms a fine, soft curd during digestion. Goats' milk is white in color, as it has practically no carotene. Goats' milk produced under sanitary conditions, and if the buck is kept separate from the does, will not usually have an unpleasant "goat" flavor and odor, though the flavor is somewhat different than that of cows' milk.[98] One should always be sure that the goats are free from brucellosis, which causes undulant fever, or Malta fever, in humans.

Good pure-bred or high-grade does

yield 1,000 to 2,000 lbs. or more of milk a year. In Illinois tests one doe produced 3,045 lbs. of milk and 94 lbs. of fat in a year.[99] At peak of production one doe yielded 19.7 lbs. a day, and another 16.5 lbs. In a California study in a high-producing herd, the average yield was 7.5 lbs. of 4 per cent fat-corrected milk.[100] (999)

It is difficult to secure a uniform supply of milk throughout the year, as most milk goats freshen in spring and their lactation periods are somewhat shorter than those of cows.

Good milk goats require about the same amounts of feed as good cows per 100 lbs. of milk produced.[101] However, the cost of producing goats' milk on a commercial basis is higher than for cows' milk, chiefly because of the much greater amount of labor required per quart of milk.

In general, the same feeds and the same care and management that are successful with dairy cows and sheep are suitable for milk goats. From 6 to 8 goats can be kept on the feed required by a cow. A suitable ration is 1 to 2 lbs. of good concentrate mixture, with 3 lbs. hay or with 2 lbs. alfalfa or clover hay and 1.5 lbs. silage or roots. On pasture, 1 to 1.5 lbs. concentrates daily are usually needed by high producers. The concentrate mixture should be similar to those used for dairy cows.

When does are fed good alfalfa hay as the only roughage, merely a mixture of grain or grain and molasses produces about as good results as a more complex concentrate mixture.[100]

1339. Angora goats.—The raising of Angora goats for their mohair is important in certain southwestern range districts, especially in Texas. For the 5-year period, 1950–1954, an average of 2,414,000 Angora goats were sheared a year in the 7 principal producing states, the average clip of mohair being 5.3 lbs.[102]

The meat from the surplus goats is sold under the name of "chevon" and is appetizing if from a well-fattened young goat. In a Texas experiment Angora wethers a year old or older made considerably smaller daily gains than Rambouillet lambs during fattening.[103] The Angoras also required much more feed per 100 lbs. gain.

In the western states the goats are usually kept under range conditions, often grazing on rough land and utilizing browse that even sheep would refuse.[104] In cut-over districts, Angora goats are occasionally used for clearing land of brush, but the area must be heavily stocked and closely grazed to subdue the brush.

QUESTIONS

1. State 4 essentials of successful flock management.
2. What kinds of pasture are most commonly used for sheep in your region?
3. On what basis would you cull a flock of ewes?
4. Discuss the breeding of ewe lambs.
5. What factors determine the best date for lambing?
6. Under what conditions are twin lambs desirable?
7. Discuss the flushing of ewes.
8. State the most important points in feeding and caring for the ram.
9. How should ewes be fed in the fall?
10. Discuss the feeding of pregnant ewes in winter.
11. Describe the care of ewes at lambing time.
12. State the most important points concerning the feed and care of ewes after lambing.
13. State the important points concerning the feeding and care of young lambs.
14. How much milk a day do ewes of the common breeds yield?
15. When is it advisable to creep-feed lambs?
16. What are the best times to market farm-raised lambs in your region?
17. What are spring lambs and where are they chiefly produced?
18. Approximately how much hay and concentrates does it require to carry a breeding ewe through the winter?
19. State 5 important factors affecting the net income from sheep.
20. Describe a method by which stomach worms and other internal parasites can be controlled.
21. How are sheep handled on the western ranges?
22. Describe any methods of fattening western lambs that are used in your district.

23. What kind of feeder lambs would you purchase to fatten for the market?
24. In commercial lamb fattening, how much gain is secured per head daily, and how much concentrates and roughage are required per 100 lbs. gain?
25. State a good ration for fattening lambs, adapted to your local conditions.
26. How should fattening lambs be started on feed?
27. Discuss the proportions of concentrates and roughage for fattening lambs.
28. How may losses from overeating disease be avoided?
29. Discuss the advantages and disadvantages of self-feeding fattening lambs.
30. If lambs are fattened on pasture in the fall in your region, describe the methods used.
31. What is the usual percentage of shrinkage of fat lambs on shipment to market? What is the usual dressing percentage?
32. State the most important facts concerning the feeding of milk goats.
33. In what districts of this country are Angora goats important?

CHAPTER XXXII

HORSES AND MULES—GENERAL PROBLEMS

I. Factors Influencing the Work Done

1340. Importance of economical feeding and care.—Although tractors and trucks have largely replaced horses and mules in the United States, in some countries they are still very important. In this country there is much interest in saddle horses and other light horses.

The discussions in this volume concerning the nutrient requirements and the feeding and care of horses deal, of necessity, chiefly with work horses. This is because nearly all of the scientific experiments with horses have been with draft horses, rather than with light horses.

However, the same general principles apply to light horses as to horses used for draft. The special points in the feeding and care of light horses are treated in the following chapter. (1376–1377)

The importance of efficient feeding of horses and mules is shown by the fact that it is often possible to save 10 to 20 per cent of the usual feed cost, with no injury and in some cases even a benefit to the animals. Also, the animals must have proper feed and care if they are to remain useful over a period of many years.

Before studying the methods of feeding and caring for horses and mules, we will briefly consider the various factors which influence the amount of work they can perform. Most of the following discussions refer particularly to horses, since nearly all of the scientific trials have been conducted with them. The same feeds may be used for mules, however, and the same principles of feeding and care apply to them. (1358)

1341. Work done by horses.—The work which horses can do depends on their weight, their muscular development, and their endurance. At steady and continuous work for 10 hours a day, the pull (or draft) for a horse should not be more than one-eighth to one-tenth its weight. For example, a 1,600-lb. horse should not be required to exert an average pull of more than 160 to 200 lbs.

For a brief interval a well-trained horse can do 10 times the normal rate of work, and can exert a pull nearly as great as his weight. A few can momentarily exert a pull even greater than their weight. The horse greatly excels all types of engines and motors in this capacity for overload.

This reserve power of a good team is of great importance in their ordinary work. For example, it may require more than 10 times as great a pull to start a loaded wagon as it will take to haul it after it is once in motion. Also, this reserve power is essential in drawing loads over uneven roads and up steep grades, or under other conditions where great effort is needed for short periods.

This great reserve power of horses is probably due to the fact that they are able to store much greater amounts of glycogen in their muscles and other tissues than other farm animals.[1] This large store of glycogen serves as an immediately available source of energy for muscular work. Horses also have a much higher rate of metabolism per unit of weight when idle than other farm animals, and about double that of man. This high rate of metabolism helps explain the capacity of the horse for work.

In measuring the rate at which horses perform work, the unit called the *horse power* is used. This is the performance of 33,000 foot-pounds of work per minute. (One foot-pound is the amount of work done in lifting one pound one foot against the force of gravity.) A horse weighing 1,500 to 1,600 lbs. is able to work steadily at the rate of approxi-

mately one horse power.[2] An ox can draw about as heavy a load as can a horse of the same weight, but ordinarily at only two-thirds the speed. The work a man can do is usually from one-tenth to one-sixth of a horse power, but for a minute or two he can exert a full horse power or even more.

The great power that can be exerted by horses is shown by a championship record made by a 4,450 lb. team in a horse-pulling contest. In such contests specially constructed dynamometers are used, in which the power to pull the dynamometer can be adjusted at various amounts. This team pulled the dynamometer the full distance required when set at a pull of 3,900 lbs. This pull was equivalent to starting a load of more than 25 tons for 20 consecutive times on a good pavement.

1342. Factors affecting the work performed.—Weight is the most important single factor that determines the amount a draft horse can pull. However, as the weight of draft horses increases, the pull they can exert per 100 lbs. live weight decreases somewhat.[3]

To perform work most efficiently, horses should have energetic but calm dispositions, and they must be well trained and driven skillfully and steadily. A nervous, excitable driver cannot get the utmost from his team. Among horses of the same weight, those with the greater heart girth and compact, muscular build are able to exert a greater pull. Horses must also be in proper flesh to do their best.

A horse cannot do the maximum amount of work unless the harness fits properly. It is especially important to have the collar fit well, in order to avoid sore shoulders. Also, when horses must be worked hard during rainy weather, the harness should have hame housing to keep the collar and shoulders dry. When properly shod, horses are able to pull more than when unshod.

The kind of roadbed is important in determining how heavy a load a horse can draw. While only 25 to 50 lbs. of draft are required after the load is started to haul a load of a ton (including weight of wagon) on a level pavement made of concrete or brick, the draft on a common earth road is 75 to 225 lbs. or more per ton.[4]

Many years ago extensive respiration experiments were conducted by European scientists to determine the nutrients required by horses for various types of work, and the effect of speed and other factors.[5] Later, similar studies were carried on by Brody at the Missouri Station [6] and Ritzman at the New Hampshire Station.[7] These investigations showed that horses perform work most efficiently when walking at a speed of 2 to 2.5 miles per hour. At a trot, nearly twice as much energy is required per mile of travel as at a walk.

The efficiency continues to become less as the speed increases, until when worked at a speed of 11.25 miles an hour, a horse can accomplish less than one-tenth of the amount of work he can perform at a moderate pace.

While a pound of additional load makes but little difference to a draft horse, with running horses the requirement of speed makes it necessary that the weight carried (rider and saddle) be as small as possible. An ounce of additional load may make a difference of a yard or more in half a mile of running.

In going up a grade, a horse must not only propel his body and the load over the ground, but also he must raise them against the force of gravity. Therefore more energy is required. For example, in ascending a grade of 10.7 feet in 100 feet, a horse expends three times as much energy per mile as when traveling on a level road. In going down a hill, if the slope is too steep the horse must spend energy in bracing himself and the load against too-rapid a descent.

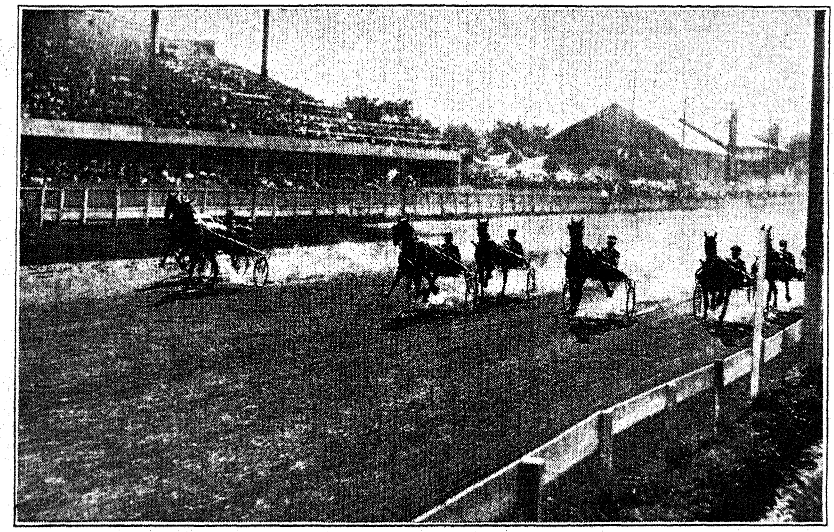
1343. Best size of horse for farm work.—The best size of horses or mules for any particular farm will depend on several factors. Farmers on level farms with large fields usually prefer heavier work animals than do farmers on hilly farms where the fields are small. On heavy soil where the draft of tillage implements is great, large size in work ani-

mals is advantageous. However, on sandy soil most farmers favor animals which are not too heavy.

Lighter horses, which can be kept more cheaply, are usually more active and will perform just as much of many kinds of farm work as extremely heavy horses. For the tillage operations which require much power, such as plowing with gang plows, the necessary power can be secured by using moderate-weight horses in teams of 3 to 5 animals, or even more.

worked at the usual rates, they converted into actual work about 20 to 25 per cent of the energy they expended during the time they were working.[9] The rest of the energy is converted into heat and is lost, so far as useful work is concerned.

However, to gain a true idea of the efficiency of the horse as a source of power, we must compute his over-all efficiency for the entire day of 24 hours. This is the percentage of the total or gross energy in his daily feed, which he



Speed Decreases the Work that Can Be Performed

A pound of additional load makes but little difference to a draft horse, but with the race horse the load must be made as light as possible.

is able to convert into useful work. Based on the amount of feed required per day, a 1,500-lb. horse working 8 hours a day at a rate of 1 horse power will have an over-all efficiency of about 8.9 per cent.

If large and small horses do amounts of work which are in proportion to their weights, their efficiencies in performing work will be equal, according to Missouri experiments.[8] On the other hand, if a large horse is not worked in such a manner as to perform an amount of labor which is proportional to his size, his efficiency will be lowered.

1344. Efficiency of the horse as a motor.—It is of interest to compare the efficiency of horses, in converting into useful work the nutrients they consume, with the efficiency of farm tractors. In Missouri experiments when horses

However, farm horses do not work every day, though they must eat every day. Therefore the over-all efficiency for the entire year is much lower than for a 24-hour period in which the horse does a good day's work. On the average, the yearly over-all efficiency of farm horses, which usually work only about 800 to 1,000 hours a year, is about 2 to 3 per cent. Obviously, any factor which in-

creases the number of hours of work a horse does during the year increases his over-all efficiency and reduces the actual cost of his labor per hour, since less of his feed will then go for maintaining him when idle.

When operated at maximum efficiency, gasoline tractors convert about 13 per cent of the energy of the fuel into the work of draft.[10] In comparing this with the efficiency of 8.9 per cent for horses in converting the energy of their feed into draft when working a full day, we must consider the following: The horse is supplied with feed in crude form, and a considerable part of it is indigestible and therefore of no value in the production of work. The gasoline or kerosene tractor, however, is not supplied with crude fuel, but with highly-refined fuel from which the waste portions have been removed. Moreover, the horse repairs his body continuously, while the tractor cannot replace the daily wear of its parts.

II. Nutrients Required by Horses

1345. Nutrients required by various classes of horses.—The chief requirement of an animal doing muscular work is a liberal supply of total digestible nutrients or net energy, as has been shown in Chapter X. For the performance of work, an animal needs but little more protein than when it is idle. Also, the requirements for minerals and vitamins are not appreciably increased by hard labor. (311) Rations that are relatively low in protein and that have only a moderate supply of minerals and vitamins are therefore entirely satisfactory for mature work horses or mules.

The chief need of mature idle horses is for heat to maintain the body temperature, and only a small amount of net energy is required. (235, 241–244) Also, the requirements for protein, minerals, and vitamins are low. Mature idle horses can therefore be fed rations that consist largely of such cheap feeds as straw or corn stover, which are low in net energy and in protein, but which produce much heat in the body.

Because of their more nervous disposition, horses allowed to move about considerably have a somewhat higher maintenance requirement than cattle or other farm animals, in proportion to their size.[11]

Brood mares need liberal amounts of protein, minerals, and vitamins during pregnancy. (288) When they are nursing foals, their requirements for these nutrients are still greater. (300) Colts likewise need a much greater proportion of protein than do mature work horses, and also more calcium, phosphorus, and vitamins.

1346. Morrison feeding standards; rations for horses.—In the Morrison feeding standards, which are presented in Appendix Table III, the requirements of the various classes of horses are stated. It will be noted that these standards show the amounts of dry matter, digestible protein, and total digestible nutrients required per head daily by horses of various live weights and of the various classes. Allowances of calcium, phosphorus, and carotene are also stated. Amounts of net energy are recommended for those who wish to compute rations according to the net-energy method.

In these standards the allowance of total digestible nutrients for a horse at hard work is about double that for an idle horse of the same weight, while there is much less difference in the dry matter. This means that the ration must consist more largely of grain and other concentrates as the work becomes harder. The approximate amounts of hay and concentrates that should be fed to horses that are at hard, medium, and light work and to those which are idle are stated in the paragraphs preceding Appendix Table III.

Horses probably differ more in temperament and in individual feed requirements than do other classes of stock. Therefore a feeding standard can serve only as a general guide as to the amount of grain any particular horse will need to keep it in proper condition.

Many different rations are suggested in Appendix Table VII for horses of various classes. These are suited to condi-

tions in various parts of the country and should be helpful in selecting balanced rations that are economical under the local conditions.

1347. Digestibility of feeds by horses.—Horses digest their feed somewhat less completely than do ruminants, but the difference is not marked, except for low-grade roughages, such as straw or poor-quality hay.[12]

Too few digestion trials have been conducted with horses to warrant separate tables of digestible nutrients for them. Therefore, in computing rations for horses, values must be used which are based upon digestion trials with ruminants, such as the figures for digestible nutrients given in Appendix Table I.

The Morrison feeding standards for horses are designed for use with these digestible nutrient values, and allowances have been made for the lower digestibility of roughages by horses. Rations will therefore be satisfactory if computed according to these standards and according to the rules for feeding concentrates and roughages that are given in Appendix Table III, immediately preceding the feeding standards.

Investigations showed many years ago that moderate work, even immediately after a horse had eaten, tends to increase the digestion and absorption of nutrients.[13] Severe labor may, however, retard digestion. Contrary to some statements, reasonable exercise does not hasten the passage of food from the stomach into the small intestine.

1348. Roughage requirements of horses.—Under usual conditions it is advisable to feed approximately the amounts of hay or other roughage advised in the paragraphs preceding Appendix Table III and in Appendix Table VII. However, when hay is relatively high in price in comparison with grain, the amount of roughage can be reduced somewhat.

For example, in Connecticut trials hard-worked horses were kept in good condition on only 8 lbs. of hay per head daily, plus a sufficient allowance of grain.[14] In Texas tests ponies grew satisfactorily on a ration of corn, dried beet pulp, and purified casein, plus minerals and complete vitamin supplements, but with no hay or other roughage except the beet pulp.[15]

In World War II German and Russian army horses in active service were satisfactorily fed compressed cakes or cubes made of mixtures of concentrates and ground roughage, in order to save space in transportation.[16]

As is emphasized in the next chapter, horses at work and light horses should not be allowed to eat all the very palatable hay that they will consume, for they may eat so much that it will be detrimental.[17] (1361)

From the limited data available, it seems that it will take 2.5 to 3.0 lbs. or more of hay to equal 1.0 lb. of corn or oats for the production of work.[18] For maintaining an idle horse in winter, hay will have a higher value, and it will probably take only 1.5 to 2.0 lbs. of hay to equal 1.0 lb. of grain in value.

1349. Requirements for protein.—It will be noted that the Morrison feeding standards recommend 0.6 to 0.8 lb. digestible protein per day for a 1,000-lb. idle horse. For horses at work somewhat larger amounts are advised, depending on the severity of the work. These recommendations are considerably lower than the amounts of digestible protein recommended in the older standards, such as the Wolff-Lehmann or the Armsby standards.

In various experiments rations having even less protein than advised in the Morrison standards have been fed successfully to idle horses and to horses at work.[19] Therefore, when protein-rich feeds are unusually expensive, mature idle horses or work horses can undoubtedly be fed for considerable periods on less protein than stated in the standards. However, for continued feeding over a long time, the author would not advise less protein than is recommended in the standards. It must be borne in mind that the digestibility of a ration may be decidedly decreased if the protein content is too low. Therefore, merely to secure efficient utilization of feed, it is not ad-

visable to use rations extremely low in protein.

In New York experiments with mature work horses, a mixture of 900 lbs. cracked corn and 100 lbs. crushed oats was just as satisfactory as one having more protein, when fed with timothy hay cut reasonably early.[20] If the hay had been late-cut timothy hay, low in protein, the results probably would have been much less satisfactory on the combination of corn and timothy hay with the small amount of oats.

1350. Mineral requirements.—Mature work horses, with the possible exception of brood mares, do not require the addition of any minerals, except common salt, to ordinary rations that contain a normal amount of good hay. This is because their needs for calcium and phosphorus are relatively low.[21]

In Iowa trials with mature work horses and in New York tests with growing colts, there was little or no benefit from adding a mineral mixture supplying calcium and phosphorus to properly balanced rations which had plenty of good roughage.[22] However, even in mature horses, serious bone injury may be caused by continued feeding of a ration that is unusually low in these minerals. This was shown in South Dakota experiments in which horses were wintered on straw alone.[23] In California studies, a decided deficiency of calcium and phosphorus in the rations of stallions seemed to cause a marked decrease in the quality of their semen.[24]

Growing colts must have an ample supply of calcium and phosphorus and also sufficient vitamin D to enable them to develop strong, sound bones. Likewise, pregnant mares and mares nursing foals require much more calcium and phosphorus than do other mature horses. Well-cured legume hay or mixed hay high in legumes is the best roughage for colts and brood mares during the winter season.

A bone disease often called "big head" may be caused in horses, donkeys, and mules by rations very low in calcium, especially when there is an excess of phosphorus.[25] (152) In this disease there is swelling of the jaws and later some of the bones of the head become greatly enlarged. The bones also become porous and frequent fractures occur. Young horses are affected more often than old ones.

In areas where there is a deficiency of iodine, brood mares should be fed iodized salt during at least the latter half of pregnancy, to avoid danger of goiter in the new-born foals. It is the belief of some that navel-ill and trouble from weakness of foals at birth may be lessened by feeding brood mares during pregnancy 14 to 15 grains of potassium iodide per head a week, with their grain.[26]

1351. Salt.—Horses should be supplied regularly with salt. An allowance of 1.75 to 2.00 ounces per head daily is sufficient, and many horses eat less.[27] A good plan is to supply salt where they can take what they wish, either loose salt from a suitable box, or block salt. Horses at hard work need more salt than others, for considerable is excreted in the sweat.

1352. Requirements for vitamins.—There are commonly no deficiencies of vitamins for mature work horses in ordinary rations that contain plenty of good hay, for their vitamin requirements are small. The vitamin needs of brood mares and colts are higher, but they will be amply met if good legume or mixed hay is fed when the horses are not on pasture.

California investigations indicate that the requirements of horses for vitamin A or carotene per unit of body weight are about the same as those for cattle, sheep, or swine.[28] In these studies a deficiency of vitamin A caused night blindness, eye injury, respiratory and reproductive difficulties, and eventually death.

Colts sometimes develop rickets, because of a lack of vitamin D or of calcium and phosphorus. This rarely happens when they have enough well-cured hay. If a colt shows any symptoms of rickets, it should be given an ounce of cod-liver oil a day, or an equivalent amount of a vitamin D concentrate. Also,

a mineral mixture should be supplied, as recommended in Chapter VI. (185)

Differing from ruminants, horses require certain vitamin B-complex vitamins in their feed. This is apparently because there is less synthesis of these vitamins in the digestive tract than in the case of cattle or sheep. (208) However, the usual rations fed horses, containing plenty of good hay, will ordinarily provide enough of the B-complex vitamins.

In a Kentucky experiment there was no benefit from adding a B-complex vitamin supplement to the usual ration fed young Thoroughbred pregnant mares.[29]

In Texas studies an artificial ration purposely made deficient in B-complex vitamins failed to produce normal growth of ponies.[30] When 10 per cent of yeast was added to provide the B-complex vitamins, the growth was satisfactory, and nearly as good gains were made when the ration was supplemented with riboflavin and pantothenic acid.

It has been reported that moon blindness, or periodic ophthalmia, in horses can be prevented but not cured by adding 40 milligrams of riboflavin per head daily to the rations of horses.[31]

1353. Watering horses.—Plenty of water of good quality is essential for horses. About 10 to 12 gallons, or 80 to 100 lbs., of water should be provided daily for each horse. In warm weather and when at hard work, horses will drink more water than at other times, owing to the greater evaporation of water from the body. They also drink more water when fed legume hay than when the roughage is grass hay.

Horses may be watered before, after, or during a meal without interfering with the digestion or absorption of food.[32] However, they should be watered at regular times. A horse that has been worked hard should be watered before being fed, but he should not be allowed much water when very warm. A moderate drink taken slowly will refresh him and do no harm.

During hot weather horses should be watered every hour or two while at hard work, for they need a frequent drink of water nearly as much as does a man under similar conditions. Taking a can or barrel of water along to the field, so the horses can be thus watered, aids greatly in preventing injury from overheating.

III. Preparation of Feed; General Problems

1354. Grinding or crushing grain; soaking feed.—For horses whose teeth are in good condition, there is no need to grind or crush corn or oats. Corn is best fed on the cob or as shelled corn. (701) Ear corn that is very hard and flinty should be ground or soaked.

Grinding oats for work horses increases the value only about 5 per cent. (724) In Michigan trials crushing a mixture of half shelled corn and half oats did not increase its value enough to justify the expense of preparation.[33] For foals up to at least 7 or 8 months of age, grinding or crushing oats is advisable.[34]

Barley, wheat, rye, and the grain sorghums should be ground or crushed for horses, because the kernels are so small that the grain is chewed less thoroughly than corn or oats. If these smaller grains cannot conveniently be ground or crushed, they should be soaked before feeding, to soften the kernels.

There is no advantage in cooking, fermenting, or predigesting feed for horses. (94–95)

1355. Chopping or grinding hay or other roughage.—Experiments have shown that chopping or cutting good-quality hay for horses does not increase its value enough to warrant the expense.[35] If the hay is of poor quality, chopping it may reduce the wastage sufficiently to be worth while. Grinding hay is not advisable for horses, as the ground hay is dusty and may irritate the nasal passages.

It generally pays to chop or shred corn or sorghum fodder or stover in order to lessen the waste. In some regions of Europe a common practice is to mix chopped straw with chopped hay, more straw thus being eaten than would be consumed otherwise.

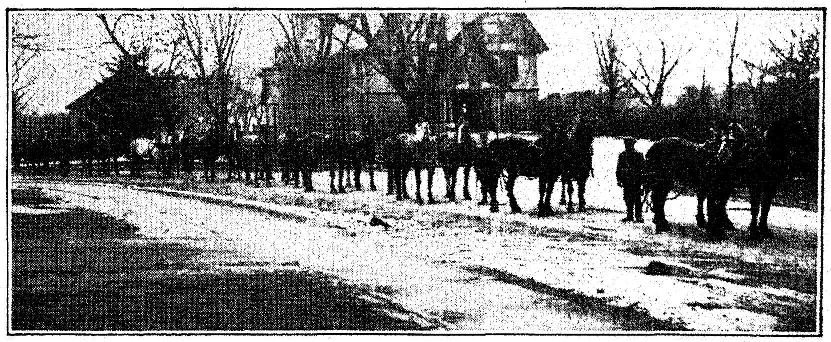
1356. Self-feeding.—The self-feeding method, which is so successful with pigs and is also used for fattening cattle and sheep, is not satisfactory for horses. Even if a mixture of cut hay and grain is fed, it is impossible to adjust the amounts of grain for the various horses so that the easy keepers are not overfed and the hard keepers underfed.

Mules can, however, be satisfactorily self-fed grain or a mixture of grain and protein supplement, with hay fed separately in a rack. Also, a mixture of grain and chopped or ground hay can be self-fed as the entire ration. When mules were self-fed grain in Mississippi tests, they did not gorge on it, as horses would have done, and there was no trouble from digestive disturbances.[36] However, they ate more grain and less hay than hand-fed mules, and the feed cost was 19 per cent higher.

1357. Hints on caring for horses.—Horses must have regular exercise for health and a long period of usefulness. Plenty of exercise is especially important for brood mares, stallions, and colts. When idle, work horses should be turned out where they can exercise.

To keep them in good health, horses should be housed in well-ventilated quarters and be protected from drafts. Cool quarters with good ventilation are far preferable to warm, close stables. The stalls should be well bedded, so the horses will be comfortable at night.

Thorough and careful grooming is necessary to remove the waste material left on a horse's coat when the sweat evaporates, and to keep the pores open and the skin healthy. As idle horses running at pasture sweat little and have abundant opportunity to roll, grooming them is unnecessary. While grooming should be thorough, a dull currycomb is preferable to a sharp one, and a brush should be used on the tender head and legs.



FARM HORSES USED IN WISCONSIN FEEDING TRIALS

Experiments during two years by the author and associates with these horses proved that crushing oats makes a saving of only about 5 per cent.

A good horseman always cares for the teeth of his horses and sees that no sharp points prevent proper chewing of the food. He also sees that the collar and harness fit well and that the horses' feet are properly cared for. He wipes collars and collar pads clean with a damp cloth each evening and allows them to dry before being used again. At the close of the day's work, especially at the start of the season, he takes time to wash the shoulders of the horses with a strong salt solution, as he knows this will help prevent sore shoulders.

A good horseman makes changes in the ration gradually, for a sudden change may cause colic. In starting the day's work he gradually warms the horses to their task before they are put to extreme exertion. In cold weather he blankets his

horses whenever the work ceases and they are forced to stand in the cold even a short time.

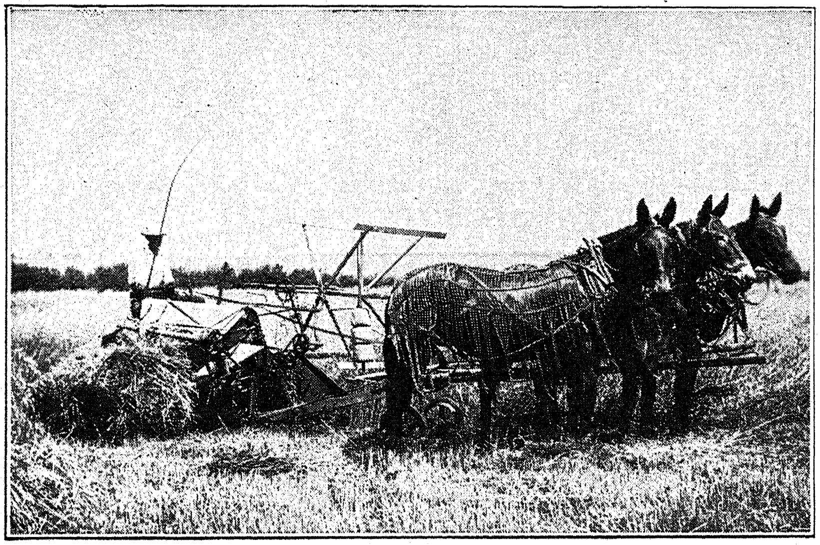
1358. Mules.—Mules are more hardy than horses and are able to give satisfactory service under adverse conditions. Also, they may require slightly less feed than horses to do a given amount of work.

Mules are generally more sensible in eating and less likely to gorge themselves than horses, and hence are less subject to colic. Indeed, mules are often fed at troughs, like cattle, and allowed to eat all they desire. They are not fastidious in their taste and will consume roughages that horses would refuse. Mules also endure hot weather better, and because of the peculiar shape of the foot and its thick, strong wall and sole, they are less subject than horses to foot lameness. These good qualities of mules are partly offset by their stubbornness and other peculiarities of disposition.

Though mules will endure more neglect than horses, good care and feed will prove profitable. For feeding mules the same feeds may be used as in the case of horses, and the same principles apply in suiting the amount of feed to the size of the animal and the severity of the work performed.

QUESTIONS

1. Define *horse power.* How heavy a horse does it take to perform 1.0 horse power of work at steady labor?
2. What factors determine the amount of work a horse can do?
3. State the various types of work that horses perform.



MULES ON A CORN-BELT FARM

Mules are the chief work animals on southern farms and are often used in the corn belt.

4. Discuss the influence of speed upon the efficiency with which horses perform work; the influence of grade.
5. What is the relative efficiency of large and small horses in doing work?
6. Discuss the efficiency of the horse as a motor.
7. Compare the digestibility of feeds by horses and by ruminants.
8. Should horses be allowed to eat all the good-quality hay they will consume?
9. Approximately what is the relative value per pound of grain and hay for the production of work?
10. Discuss the nutrient requirements of horses under the following headings:

(a) Protein; (b) salt; (c) other minerals; (d) vitamins; (e) water.

11. Are the following methods of preparing feed for horses advisable; (a) Grinding corn; (b) grinding or crushing oats; (c) grinding barley, wheat, or grain sorghum; (d) chopping hay; (e) grinding hay?
12. Discuss the use of self-feeders in feeding horses and in feeding mules.
13. Mention some important points to be observed in caring for horses.
14. What advantages and disadvantages do mules have in comparison with horses?

CHAPTER XXXIII

FEEDING AND CARING FOR HORSES

I. Feeding Work Horses

1359. Many feeds suitable for horses and mules.—In most localities the usual ration for horses and mules consists of only one or two kinds of grain, with no more variety in the roughages. Over much of the United States oats are the grain most commonly fed to horses, and some horsemen consider them indispensable. However, entirely satisfactory results are secured with grain mixtures that contain no oats, but which are balanced in nutrients and have the proper bulkiness.

Many experiments have shown that in making up rations for horses, just as for other stock, the prices of the different available feeds should always be considered. A ration should be selected that will be as cheap as possible, yet entirely satisfactory for keeping the animals thrifty and efficient over a long period of usefulness.

It is more important for horses than for other stock that the feeds be of sound quality and not moldy, spoiled, or extremely dusty. This is because horses are especially apt to be injured by damaged feeds, and dusty hay or fodder greatly increases the trouble from heaves.

The composition and value of the many feeds that may be fed to horses and mules are discussed in the various chapters of Part II.

The experiments conducted to study problems in feeding and caring for work stock have nearly all been with horses, and few have been with mules. Therefore most of the discussions in this chapter deal with horses. However, the same general principles apply in feeding and caring for mules as in the case of horses.

The discussions in this chapter deal chiefly with the feeding and care of draft horses. However, brief summaries are given later concerning the special requirements of saddle horses and other light horses, including race horses.

1360. Grains and other concentrates for horses and mules.—Because of their bulky nature, oats are the safest of all common grains for horses and mules, as has been emphasized in Chapter XX.

However, corn, barley, wheat, and the grain sorghums can all be used successfully in place of oats, when fed as advised in the chapters in which these grains are discussed. Ground or crushed rye should not form more than one-third of the concentrate mixture. Hominy feed is a satisfactory substitute for oats, and molasses is sometimes fed to horses as an appetizer or conditioner, or as a grain substitute when cheap in price.

Among the protein supplements, wheat bran is especially useful because of its bulky nature and its laxative effect. Linseed meal is deservedly popular on account of its laxative and conditioning effect. Other protein supplements, such as soybean oil meal, cottonseed meal, and corn gluten feed, can be used for feeding horses and mules, as has been stated in the chapters of Part II.

1361. Hay and other roughages for horses and mules.—In the northern states timothy hay is the standard roughage for horses and mules, and in the South hay from other grasses, such as Bermuda grass, Johnson grass, or Dallis grass. One of the reasons for the popularity of grass hay for horses and mules is that it is usually free from mold or dust. Also, grass hay much more nearly approaches legume hay in actual nutritive value for feeding work horses or mature light horses than it does for other classes of stock. This is because of the low requirements of such horses for protein, minerals, and vitamins. (**1345**)

Well-cured legume hay or mixed

legume-and-grass hay is entirely satisfactory for horses and mules, if it is properly fed. The common prejudice against legume hay for horse feeding is due to the use of poor-quality hay or to feeding an excessive amount. Horses are so fond of good legume hay that they are apt to eat too much for their own good, if such hay is fed too liberally. They should therefore be fed no more than they need. Since good legume hay is higher in digestible nutrients than most grass hay, less of it is needed to replace a given amount of grass hay.

TIMOTHY POPULAR FOR HORSES

Timothy hay and other grass hays are the standard roughages for horses and mules.

It is important that legume or mixed hay for horses be bright and well cured, for that which is moldy or dusty may cause heaves. Dampening dusty hay before feeding helps somewhat, but it is far better to prevent mold and dust by proper curing.

Well-cured corn or sorghum fodder or stover can be substituted for hay in feeding horses and mules, especially those that are idle or at light work. Straw can also be used as a considerable part of the roughage for wintering idle work stock. If better roughage is scarce, some straw can even be used for work horses in place of hay. In such a case, it had best be chopped and mixed with the concentrates.

Silage of good quality, free from decay or mold, may replace one-third to one-half the hay usually fed to horses and mules. Poor quality silage should never be fed to horses, for they are much more susceptible to injury from spoiled silage than are other stock. Horses and mules should be accustomed to silage gradually. Because of its bulky nature, horses at hard work should not be fed much silage, but it is well suited for idle horses, brood mares, and growing colts.

1362. Pasture.—Through the well-planned use of pasture, the cost of keeping farm work horses and mules can usually be decidedly reduced. Good pasture is even more important for colts and brood mares.

Whenever farm work animals are idle during the pasture season, they should be turned to pasture, thus reducing the labor and expense to a minimum. Even when horses are worked regularly, it is best to turn them out at night, after they have eaten their grain, into a near-by pasture which has been fertilized so that there is plenty of grass. This not only reduces the cost of feed but also helps to keep them thrifty. During hot weather, horses are much more comfortable at night when turned out to pasture than when kept in the stable.

The saving in feed that can be made by such use of pasture is shown by Mississippi experiments.[1] In a 3-year test, work mules which had access to good pasture at night and on idle days during the grazing season needed about 25 per cent less grain and 50 per cent less hay than their teammates which had no pasture. The mules having pasture also gained 50 lbs. more per head and were as efficient workers as those not pastured.

Work stock should not be turned on pasture too early in the spring, as the grass is then too laxative. Also, it is best to accustom them to pasture gradually, and the pasturing should be regular, and not intermittent. When work horses are pastured, the other feeds should not be of a laxative nature.

After the harvest is over in the fall, horses not needed for work should be turned to pasture. They should have

access to a shed and some good-quality dry roughage should be fed in a rack, to supplement such feed as they can secure from stalk and stubble fields and from meadows. Where there is little snow in winter, idle horses can get no small part of their winter feed by cleaning up such fields.

Colts and also brood mares which are not at work should be on good pasture throughout the growing season, care being taken that they actually have enough feed to keep them thrifty. City horses are often turned on pasture so that their feet may recover from the ill effects of hard pavements.

For early spring and for fall pasture, bluegrass or other permanent pasture is excellent. Mixed pasture that contains considerable white clover or other legumes is even better than grass alone.

The use of pastures grown in the regular crop rotation, instead of parasite-infested permanent pasture, will help greatly to reduce trouble from internal parasites. Since horses are much less subject to bloat than are cattle or sheep, alfalfa and other legume pasture is excellent for them. Such mixtures as alfalfa and bromegrass furnish ideal pasture.

1363. Feeding work horses.—As a guide in selecting economical rations for work horses, several example rations are given in Appendix Table VII for 1,200-pound horses which are at hard, medium, and light work and for horses which are idle. All these rations meet the requirements according to the Morrison feeding standards and should prove satisfactory in practice. With horses of other weights, the rations should be increased or decreased by approximately one-twelfth the amounts of feed shown, for each 100 lbs. the live weight differs from 1,200 lbs. A horse that is a hard keeper will need considerably more grain than an easy keeper doing the same amount of work.

Usually the daily amount of grain or other concentrates is divided equally into 3 feeds, and given at morning, noon, and night. It is best to feed only a small amount of hay in the morning, so the horse's digestive tract will not be too much distended when he is at work. A common plan is to feed about one-fourth the daily allowance of hay in the morning, one-fourth at noon, and one-half at night. Some omit the noon feeding and give one-third the hay in the morning and the remainder at night, when the horses have plenty of time to eat it.

Horses that are inclined to bolt their grain, or eat it too rapidly, can be made to eat more slowly by placing in the feed box several smooth stones about 3 inches in diameter, or a few whole corn cobs. Another method is to feed the grain well spread out in a large, flat feed box, or else to mix it with bran or chopped hay.

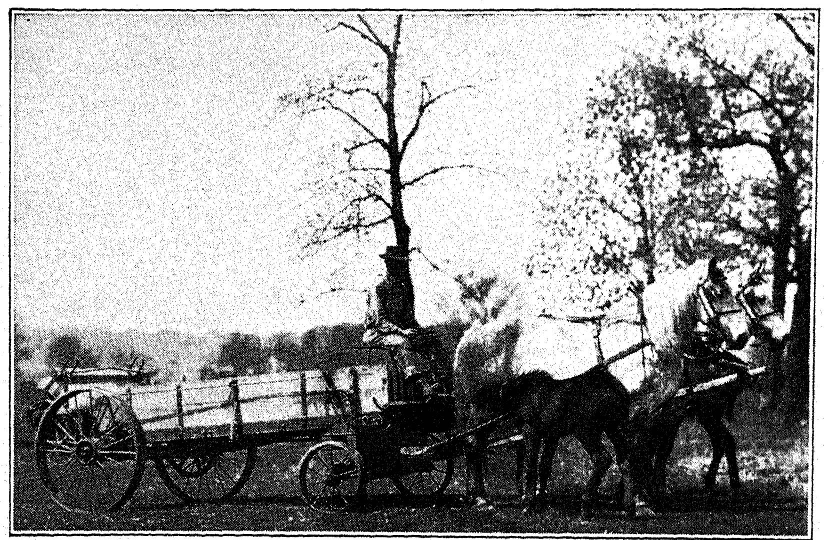
To avoid digestive troubles and possible deaths from azoturia, the allowance of grain for horses at hard work should be reduced on idle days to 50 to 70 per cent of the amount usually fed. It is best to feed on such days in place of the grain, a mixture of two-thirds grain and one-third bran. Some feed a small allowance of grain at noon on idle days, with only a bran mash both morning and night.

On coming to the stable at noon, the work horse should have a drink of fresh water, care being taken, if he is warm, that he does not drink too rapidly, or too much. Before going to work, he should be watered again. If possible, an hour should be allowed for the mid-day meal, and some horsemen remove the harness so the horse can eat his meal in comfort and rest easily. When the horse comes in after the day's labor, he should be given a drink, unharnessed at once, and when the sweat has dried, brushed well. Horses will also appreciate a drink in the evening after they have eaten most of their hay.

1364. Wintering farm horses.—When farm horses are idle during the winter, they should be maintained largely on cheap roughage. Idle horses can get much of their feed in fall and early winter by grazing the aftermath in meadows or by cleaning up stalk and stubble fields. Often they can be fed the refuse stems from clover or alfalfa hay which

has been fed to other stock. Straw or stover from corn or the sorghums can also form a considerable part of their ration, but care should be taken to supply some feeds higher in protein, minerals, and vitamins, or bad results may follow. If not provided more liberally, it is wise to feed 5 lbs. per head of legume hay at least 3 times a week. Light grain feeding should begin a few weeks before spring work starts, to get the horses into condition for work.

Idle horses should be turned out daily in winter for exercise in a lot that is protected from the wind. If they have the run of fields during the winter, they should have access to a dry shed for shelter, except where the weather is mild.



A Good Team of Brood Mares

Such mares can do farm work most of the year and also raise good colts.

II. Raising Horses; Feed Requirements

1365. Feed and care of brood mares.—It does not take very much more feed to keep a brood mare throughout the year than it does to feed another horse doing an equal amount of work.

Good results cannot be secured, however, unless a brood mare has proper feed and care. It is estimated that only 60 per cent of the brood mares that are bred each year produce living foals. This enormous loss is largely due to neglect and carelessness.

Idleness must be avoided in the case of brood mares. The best exercise is regular work, yet judgment must always be used in working brood mares. Pulling too hard, backing heavy loads, wading through deep snow or mud, or other over-exertion is dangerous. When not worked, a mare should be turned out daily for exercise. As foaling time approaches, the work should be lightened, and preferably discontinued 3 days to a week before foaling. When laid off, the mare should still be allowed to exercise. Mares heavy in foal are apt to be cross and quarrelsome, but they should always be handled gently.

The rations for brood mares should contain liberal amounts of protein, calcium, phosphorus, and vitamins. An abundance of these nutrients is especially needed by mares that are suckling foals and by young mares that are still growing. Several example rations for mares suckling foals are given in Appendix Table VII.

To supply sufficient protein, min-

erals, and vitamins, it is desirable that at least half the roughage for brood mares during the winter be legume hay. The rest may be grass hay, corn stover, corn silage, or even good straw. Brood mares which are idle during the winter need but little concentrates, if they have plenty of good roughage. Sufficient grain or other concentrates should be fed, if needed, to keep the mares in thrifty condition, but they should not become fat. Constipation should be prevented by using such feeds as bran or linseed meal.

1366. Gestation period and foaling time.—The average gestation period for mares is about 11 months, or 335 days, though it may vary considerably. In California studies the gestation period of Arabian mares bred from December through May averaged 10 days longer than of mares bred the rest of the year.[2]

Shortly before foaling, the grain allowance should be decreased and enough bran or other laxative feeds used so that the mare will not be constipated. Unless the mare can foal on pasture, a roomy box stall should be provided, which has been thoroughly cleaned and disinfected to avoid infection that may cause navel ill and joint disease. The stall should be kept well cleaned and should be bedded with dry straw. If the mare has difficulty in foaling, a veterinarian should be secured.

The mare should be given a half bucket of lukewarm water before foaling, and when on her feet again she will need another drink. A light feed of bran is suitable for the first meal, and this may be followed by oats, or by such a mixture as oats and bran. After foaling, the mare should be confined for a few days, her ration not being too abundant. If all goes well, after 4 or 5 days she may be turned to pasture, and in 10 days, if work is urgent and the mare has fully recovered, she may go back to light work, for a part of the day at least.

Farm mares should not usually be bred until they are 3 years old. Breeding a well-grown draft filly at 2 years will, however, not be noticeably detrimental to her, if she is well fed and cared for.

1367. The foal.—To reach good size at maturity, a foal should make about half its entire growth during the first year. It should therefore be fed liberally, so that its growth will not be checked at any time. Soon after birth, the foal should get the colostrum, or first milk, of its dam, because this increases the resistance of the digestive tract to bacterial infection. If the foal is constipated, a dose of castor oil or a rectal injection may be necessary. On account of the great danger from navel and joint disease, the stump of the navel cord should be carefully disinfected.

If the dam does not supply enough milk, she should receive feed that will stimulate her milk flow. Good pasture is best, but if this is not available, she should have a liberal amount of grain. On the other hand, an oversupply of milk or milk too rich in fat may cause indigestion in the foal. The dam's ration should then be reduced and some of her milk drawn, the foal being allowed the first portion, which is the poorest in fat.

1368. Mare's milk.—Mare's milk is white or bluish in color with an aromatic, sweetish, slightly bitter taste. As is shown in Appendix Table I, it is much lower in fat, protein, and mineral matter than is cow's milk, but it is somewhat richer in milk sugar. The milk yield of good brood mares is greater than is often supposed. In German tests the daily milk yield of draft brood mares suckling foals was 26 to 77 lbs.[3]

1369. Raising the orphan foal.—If a mare dies, the foal may, with proper care, be raised on cow's milk. In case the foal has not secured colostrum from its dam, it will be necessary for the veterinarian to provide a substitute by the hypodermic injection of horse serum, or by other means.[4] **(270)**

As mare's milk contains much less fat but more sugar than cow's milk, the milk should be modified for a very young foal. Choose a cow in the first part of the lactation period and one giving milk low in fat, if possible. To 1 pint of milk add one-fourth pint of limewater and 1 teaspoonful of sugar. This will be enough for 2 feedings at first. Feed the foal about every hour for the first day or so, warming the milk to 100° F. and using an ordinary nursing bottle with a large nipple. This must be carefully cleansed and sterilized.

If the foal is doing well, the amount of milk may be gradually increased and the period between feedings lengthened, until the foal is fed only 4 times a day. After a few

days unmodified whole milk may be substituted and the foal taught to drink from a pail. In 5 to 6 weeks sweet skimmilk may gradually replace the whole milk and after 3 months the foal may be given all it will drink 3 times a day. As soon as possible, the foal should be fed solid food, such as crushed or ground oats, bran, a little linseed meal, and legume hay. It should also have the run of a paddock where there is good grazing.

1370. Weights and gains of colts.—At the Iowa Station the average birth weight of Percheron and Belgian colts for 4 years was 159 lbs.[5] At a year of age these liberally-fed colts averaged 1,105 lbs.; at 2 years of age, 1,506 lbs.; and at 3 years of age, 1,619 lbs.

At Macdonald College, Canada, draft colts weighed somewhat less at birth, averaging 120 lbs.[6] Their average weights at various ages were as follows: 6 months old, 730 lbs.; 1 year, 1,020 lbs.; 18 months, 1,350 lbs.; 2 years, 1,480 lbs.; 3 years, 1,790 lbs.; and 4 years, 1,980 lbs. During the first 6 months the colts gained an average of 3.4 lbs. a day; from 6 months of age to a year of age, 1.6 lbs. a day; from a year of age to 18 months of age, 1.8 lbs. a day; during the next 6 months, 0.7 lb. a day; during the third year, 0.9 lb. a day; and during the fourth year, 0.5 lb. a day.

Allen found that 1,071 trotting-bred foals averaged 110 lbs. at birth.[7] Their average gain was 534 lbs. for the first year, 264 lbs. for the second, 118 lbs. for the third, and 76 lbs. for the fourth, making their average weight 1,102 lbs. at 4 years of age.

Hooper found that Thoroughbred fillies which were foaled from the latter part of February to the end of April averaged 760 lbs. in weight and 14 hands 2 inches in height on April 1 of the next year.[8] Colts averaged 780 lbs. at the same age.

1371. Feeding the foals.—Foals should learn to eat grain as early as possible, so that they will grow rapidly. Also, if the mares are working, the foals will fret less for them. If the feed box is placed low, a foal will begin nibbling from the mother's supply at 3 or 4 weeks of age.

Crushed or ground oats and wheat bran are excellent feeds for young foals, and also such a mixture as 4 parts by weight of ground corn, 3 of bran, and 1 of linseed meal. By the time they are to be weaned, foals should be eating 2 to 3 lbs. of concentrates a day. They should also be given good legume hay as soon as they will eat it, and they should have access to a supply of good water.

If the dam has insufficient milk, the foal may be fed cow's milk, preferably milk low in fat. Constipation may be relieved by adding linseed meal to the ration. If a foal has diarrhea, the feed for both dam and foal should at once be lessened.

If the mares and foals are on pasture, a small enclosure, called a "creep," should be made at a spot where the horses are inclined to loiter, with a gate and also an opening of such size that the foals can enter, while the mares are kept out. Here a suitable grain mixture should be supplied in a feed trough. To accustom the foals to eating in the creep, the gate should be left open for a few days, so the mares can enter and eat the grain mixture. After the mares are shut out, a salt block or a large lump of rock salt can be kept nearby, so the mares will loiter near the creep.

When the mares are worked, it is usually best not to have the foals follow them. A small pasture paddock should be provided for the foals, with a shed for shelter. Burlap sacks hung from such a shed will brush flies off the foals as they pass under them. The mare should be brought to suckle the foal in the middle of the forenoon and afternoon for the first 2 or 3 weeks. Before turning her with the foal, she should be allowed to cool off, and perhaps some of the milk drawn from her udder. If the foal is housed in the barn during the day, it is well to turn both dam and foal to pasture at night. Brood mares at work should be fed a liberal amount of concentrates, so they will keep up a good milk flow.

1372. Weaning.—At from 4 to 6 months of age, the foal should be weaned. When the mare is bred soon after foaling, or if for any reason the dam or foal is not doing well, it is best to wean comparatively early. On the other hand, if the mother has a good flow of milk and her services are not needed, the foal may be allowed to suckle for

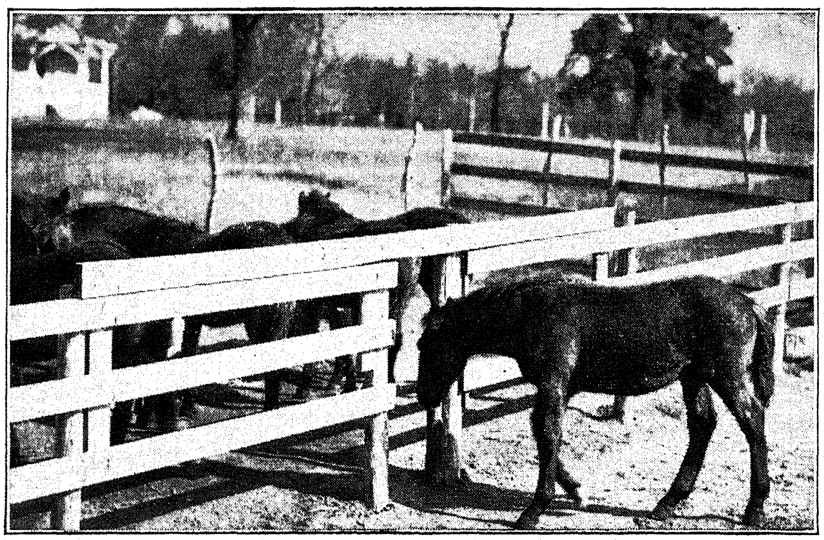
6 months. If the foal is accustomed to eating grain, weaning will cause little, if any, setback.

To wean the foal, it should be separated from its dam and not allowed with her again until they have forgotten each other. The grain allowance of the mare should be reduced till she is dried off, and her udder partly milked out when necessary.

The education of the colt should not be postponed until it is time to "break" him for work. The breaking process will be much easier and the colt will usually make a better-behaved horse if the training starts early. When still a foal, he should be taught to lead at the halter, stand tied in the stall, and display proper stable manners. Well-grown colts may be broken when 2 years old and used for limited work, thus reducing the cost of raising them considerably.

1373. After weaning.—Foals should be kept growing thriftily after weaning, by giving them a liberal amount of feed that supplies plenty of protein and also sufficient vitamins and minerals, especially calcium and phosphorus.

During the pasture season foals should have first-class pasture. Legume pasture or mixed legume-and-grass pasture is excellent. Well-fertilized pasture not only produces more rapid gains than poorer pasture, because of the more abundant feed, but it also tends to develop better bone. In a Georgia test, mule colts pastured on rather poor land which had been fertilized with calcium and phosphorus grew more rapidly and had better bone development than others on unfertilized pasture, even though the latter pasture provided plenty of forage.[9]



A CREEP FOR FEEDING FOALS ON A PASTURE

For foals on pasture with their dams, a creep should be provided, such as this, where the foals can have access to a separate supply of grain or other concentrates.

For roughage during the winter, well-cured legume hay or mixed legume-and-grass hay is the best. If the amount of such hay is limited, at least one feed of it should be provided daily, if possible. The rest of the roughage can be hay from the grasses, well-cured corn or sorghum fodder, or silage from corn or the sorghums.

With good legume hay for roughage, excellent results will be secured with oats as the only concentrate for colts, or from such mixtures as the following:

(1) Equal parts by weight of oats and either corn or barley; (2) a mixture of 3 or 4 parts oats by weight and 1 part wheat bran; (3) a mixture of 3 parts corn and 1 part wheat bran; (4) a mixture of 2 parts corn, 2 parts oats, and 1 part wheat bran.

When the roughage is chiefly grass hay or other low-protein forage, a concentrate mixture higher in protein should be used, such as one of the following: (1) A mixture of 3 parts oats by weight, 3 parts corn, 3 parts bran, and 1 part linseed meal or other protein-rich supplement; or, (2) a mixture of 3 parts corn, 3 parts bran, and 1 part protein-rich supplement.

Many expert horsemen believe that foals develop better quality of bone when the concentrate mixture is made up largely of oats instead of corn, but corn is satisfactory, if care is taken to supply plenty of protein and minerals in the ration, preferably by feeding legume hay.

In raising colts for farm work horses, the cost should be kept as low as possible by the use of a maximum amount of pasture, hay, and other roughage, and a minimum amount of grain or other concentrates. Colts raised in this manner will not be as heavy at 3 years of age as those fed a liberal amount of grain in winter, but they will be nearly as large at maturity and will be just as good work horses.

In a Michigan experiment draft colts raised from weaning on a very liberal amount of grain with what hay they would eat in winter and good pasture in summer averaged 1,574 lbs. in weight and 63.8 inches in height as 3-year-olds.[10] Other colts fed only one-third as much grain, with straw in abundance and a limited amount of hay in winter and good pasture in summer, weighed 1,347 lbs. as 3-year-olds and were 63.0 inches tall. When the colts in the groups reached maturity, there would have undoubtedly been considerably less difference in their weights.

The first group had received from weaning time to 3 years of age an average of 7,360 lbs. concentrates (nearly all oats and ear corn), 7,960 lbs. hay and 240 lbs. straw, in addition to pasture. The other colts had received an average of only 2,380 lbs. concentrates, with 6,400 lbs. hay, 3,720 lbs. straw, and pasture during the summers.

The cost of feed to 3 years of age was 70 per cent more for the liberally-fed colts than for the others. However, they were sufficiently well grown at 2 years of age so that they could have been put to some work. This might have paid for much of their feed the following year.

To reduce the cost of raising colts still further, in other Michigan trials draft colts were fed no concentrates at all after weaning.[11] They were wintered the first and following winters on hay stacked in a pasture field that had not been grazed the previous summer. They had access to a shed for shelter, but usually preferred the shelter of the hay stacks. On this hay, eaten from the stack, and the dried pasturage in winter and with good pasture in summer, they reached an average weight of 1,504 lbs. at 3 years of age. It was estimated that they had eaten an average of about 13,800 lbs. of hay and dried pasturage in the 3 winters. Colts thus wintered chiefly out of doors developed better feet and legs than those wintered in the barn and turned out for exercise daily.

If it is desired to have draft colts make maximum growth to 3 years of age, they will need 5 to 10 lbs. of concentrates a day during the first winter in addition to plenty of good roughage. During the second summer they will need 3 to 6 lbs. of concentrates a day, and during the second winter 6 to 12 lbs. The third summer they will need no concentrates if the pasture is excellent, but if the pasture is none too good, 4 to 5 lbs. of concentrates per head daily may be needed to keep the colts growing rapidly. The third winter the colts will need about the same amount of concentrates as during the second winter.

1374. Feed and care of the stallion.—Nothing so vital to the well-being of the stallion is so often neglected as

proper exercise. The best exercise is actual work, and even during the breeding season a half day's work each day is beneficial. When real work is impossible, the stallion should be turned out daily into a roomy paddock, or should be exercised on the road for a mile, or preferably considerably more.

The ration of the stallion should consist of first-class, wholesome feeds, supplying ample protein, mineral matter, and vitamins for thrift and vigor. It has been mentioned previously that a lack of calcium and phosphorus in the ration of stallions seems to decrease the quality of the semen. (**1350**) In Mississippi investigations the ration also had a marked effect on sperm production.[12] Even with legume hay (lespedeza) as the roughage, a concentrate mixture of 65 parts oats, 25 parts wheat bran, and 10 parts wheat or corn, plus 1 ounce of calcium supplement per head daily, was found to be decidedly superior to using corn as the only concentrate.

For roughage, well-cured mixed legume and grass hay is unexcelled. Pure legume hay is entirely satisfactory, if it is not dusty and if no more is fed than is actually needed.

The following concentrate mixtures are well suited for use with timothy hay or other non-legume roughage: (1) Oats 4 parts by weight, and wheat bran 1 part; (2) oats 4 parts, corn 6 parts, and wheat bran 3 parts; (3) oats 4 parts, corn 4 parts, and linseed meal 1 part. For mature stallions oats can be used as the only concentrate, even when no legume hay is fed. If a considerable proportion of the roughage fed a stallion is legume hay, a mixture of grain alone is satisfactory, even for young stallions. It may, however, be desirable to include a little wheat bran in the mixture, merely for its laxative effect. Even with legume hay as the only roughage, most horsemen prefer not to include more than one-half corn in the grain mixture for stallions.

The stallion should be fed just enough concentrates to keep him in vigorous, thrifty condition, but he should not be allowed to get fat. During the breeding season he will need as much grain as a horse at hard work, and he should be fed enough to prevent him from running down in flesh.

1375. Cost of keeping farm horses.—The most extensive data on the feed required annually by farm horses are studies for the year 1929, made by the United States Department of Agriculture on 736 corn-belt farms.[13] On these farms horses working an average of 691 hours a year consumed annually the following average amounts of feed per head: Oats, 1,565 lbs.; corn, 1,730 lbs.; other concentrates, 18 lbs.; legume and mixed hay, 2,260 lbs.; non-legume hay, 1,060 lbs.; and straw and stover, 1,640 lbs.; with 4.4 months of grass pasture and 1.7 months of grazing on corn stalk and stubble fields.

The cost of the feed was 81 per cent of the total annual net cost, after allowing credit for the value of the manure and a pro-rata credit for colts produced by a few of the mares. At 1929 prices, the net cost per hour of horse labor was 14 cents.

The ways in which the cost of feed can be kept low have been emphasized previously in this chapter. Idle horses or mules must be wintered economically, largely on cheap feeds, such as straw, corn fodder or stover, or waste feed from stubble fields, stalk fields, and meadow aftermath. The efficient use of good pasture, including night pasture for work animals, will also reduce the cost of horse labor. Improper shoeing or a poorly-fitting collar may reduce the capacity for work just as much as feeding an inadequate ration.

The cost per hour of labor will also depend largely on the number of hours of work actually performed a year. Therefore the work should be so planned as to use draft animals efficiently.

Many horses and mules are badly rundown in condition and even unfit for work as a result of severe infection with internal parasites. Proper treatment with suitable vermifuges will produce a striking improvement in their condition, save much feed, and greatly reduce the trouble from colic. Since there is more danger

to horses in administering doses of a vermifuge than in the case of other stock, the treatment had best be given by a veterinarian.

III. Feed and Care of Light Horses

1376. Feeding and caring for light horses.—Because they are generally not exercised for many hours a day, saddle horses and other light horses kept mainly for pleasure usually need less feed in proportion to their weight than do work horses at hard or medium work. All feeds should be of good quality, and the hay should be free from dust or mold.

A common allowance of hay is 1.0 to 1.1 lbs. daily per 100 lbs. live weight. About 1.0 lb. of oats or other concentrates per 100 lbs. weight should be enough for horses ridden or driven a moderate amount daily. Concentrates are commonly fed 3 times a day, the evening meal being the largest.

Oats are superior to any other single grain or concentrate for light horses.[14] However, a suitable combination of other grain and some bulkier feed gives good results, just as in the case of work horses. In case the horse is at all constipated, bran should be fed, dry or as a mash. On the other hand, light horses should not be fed too large amounts of such laxative feeds as alfalfa or clover hay or bran.

The period of satisfactory service of light horses is often lessened because they are overfed and exercised irregularly or too little. On days when they get little exercise, the usual amount of roughage may be fed but the grain allowance should be reduced, as in the case of work horses. (1363)

The amount of feed needed by saddle horses used on ranches or farms for handling stock will depend on the amount of work they actually perform. During much of the year such horses can get most of their feed from suitable pasture that is close at hand.

1377. Feed and care of race horses.—The same general principles apply to the raising of Thoroughbreds and other race horses as in the case of other horses, except that expense is not spared in providing rations that will insure proper development. The rations and methods differ to a considerable extent on various noted farms where race horses are raised.[15] This shows that there is no one best way of raising such horses. However, there is general agreement in certain practices and methods.

Commonly, excellent pasture is provided for brood mares, stallions, and colts throughout the growing season. In winter, care is taken to insure abundant exercise during the daytime in suitable paddocks or pastures. Because of its higher content of protein, vitamins, and calcium, mixed hay or legume hay of first-rate quality is generally preferred to straight grass hay.

A sufficient amount of concentrates is fed to keep the mares and stallions in the desired condition and to produce rapid growth in the colts. There is considerable difference in the concentrate mixtures used on the various farms. Oats are the most popular grain on Kentucky horse farms and commonly form a large part of the concentrate mixture.

Often cracked corn or shelled corn is included in the mixture and sometimes cracked or rolled barley. Wheat bran and linseed meal are common ingredients, and sometimes a molasses feed is added. Generally, the horses are given access to bone meal or to a mineral mixture furnishing calcium and phosphorus, so they will have a plentiful supply of these bone-building minerals.

Often yearlings that are to be sold in the spring are fed a very liberal amount of concentrates in winter, so they will not only make rapid growth but will also become fat and appear more attractive to purchasers. Opinions have been expressed that this practice may be decidedly detrimental.[16] It is believed that it may tend to produce horses with feet and legs that will not stand the strains of racing so well as when the yearlings are fed for only normal growth.

During the training and racing season, the amount of hay for a race horse must be strictly limited. Often only 7 or 8 lbs. of hay are fed a day.[17] Some horses

must be muzzled to prevent them from eating the bedding.

The allowance of oats or of concentrate mixture will range from 8 to 10 lbs. a day up to 13 lbs. or more. During the training period, a bran mash about once a week helps to keep the horse's bowels in proper condition.

QUESTIONS

1. Discuss the value of grass hay and of legume hay for horses and mules. What kinds of hay are generally fed to them in your region?
2. Why are oats so popular for feeding horses? How can other grains be satisfactorily substituted for oats?
3. Discuss the importance of pasture in reducing the cost of keeping work horses and mules.
4. State some of the most important points in feeding work horses. About how great an amount of concentrates and roughages combined should be fed daily to work horses per 100 lbs. live weight?
5. What sort of rations should be used for wintering idle farm horses?
6. Discuss the feed and care of brood mares: (a) Previous to foaling; (b) at foaling time.
7. Discuss the feed and care of the stallion.
8. Summarize the important points in feeding and caring for foals: (a) Before weaning; (b) at weaning time; (c) after weaning.
9. Approximately how much total concentrates and how much roughage does it take to raise a draft colt to 3 years of age: (a) When it is fed a liberal amount of grain; (b) when only enough grain is fed to produce satisfactory growth?
10. What are the chief items of expense in raising draft horses?
11. How can the cost of horse or mule labor be reduced to a minimum?
12. State a satisfactory ration for a saddle horse or other light horse.

CHAPTER XXXIV

GENERAL PROBLEMS IN SWINE HUSBANDRY

I. Economy of Pork Production

1378. Efficiency of pigs as meat producers.—It has been pointed out in Chapter XII that pigs excel all other farm animals in the efficiency with which they convert feed into edible meat. (**351–352**) They require much less feed and less total digestible nutrients for each pound of edible meat produced than do other farm animals.

Pigs yield a higher percentage of dressed carcass than do other meat animals; a larger proportion of the carcass is edible; and pork is richer in energy than other meat, because of a higher content of fat and a slightly lower percentage of water. However, beef and mutton usually furnish a higher percentage of protein than does pork.

Pigs have a greater capacity to consume feed in proportion to their live weights than do calves or lambs. Because of this and also because of greater efficiency in the utilization of food nutrients, they make much more rapid gains in proportion to their live weights. Well-fed pigs make more than twice as great a gain per 100 lbs. live weight from weaning time to market weights as do fattening calves, and three times as much as is made by fattening lambs.

Other advantages of swine, in addition to their efficiency in food production, are that they are very prolific and they do not require expensive buildings. Also, they are especially suited to utilize feed that might otherwise be wasted, such as garbage and garden waste. In countries where the density of population presses most upon the food supply, both swine and poultry often get most of their food from such sources. In contrast, in the United States pork production is most important in the corn belt and other districts where grain is abundant.

1379. Efficiency and rate of gain of pigs of various ages.—The amount of feed required for 100 lbs. gain in weight is lowest for young pigs and steadily increases as they grow older and become fatter. This is due to the factors which have been discussed in detail in Chapter IX. (**265**) First of all, the gain made during the early stages of growth or fattening contains more water and much less fat than when the animal becomes older and fatter. Less energy is therefore required to produce these early gains in weight. Also, since young animals eat considerably more feed per 100 lbs. live weight than do older ones, they have available for meat production a greater surplus of nutrients after their maintenance requirements are met.

As has been stated previously, these factors fully account for the lower cost of the gains made by young animals. Though they require less feed per 100 lbs. gain and therefore make cheaper gains, young animals do not utilize any more efficiently the feed consumed beyond the amount they need to maintain their bodies. As a matter of fact, in Missouri experiments where the entire carcasses of pigs were analyzed at various stages of growth up to 300 lbs. live weight, the older pigs apparently required slightly less feed than the younger ones per therm of energy in the gains they made.[1]

From a study of the results of various feeding experiments, a special committee of the National Research Council states that thrifty pigs fed modern, efficient rations will consume about the amounts of feed per head a day and make the daily gains shown in the following table.[2] The feed required per 100 lbs. gain is shown in the last column.

The rates of gain and the feed efficiencies shown in this table can be secured only when well-bred pigs are fed

first-class rations and when the care and management are excellent.

Feed consumed, gain, and efficiency at various weights

Live weight Lbs.	Air-dry feed Lbs.	Daily gain Lbs.	Feed per 100 lbs. gain Lbs.
25	2.0	0.8	250
50	3.2	1.2	267
100	5.3	1.6	331
150	6.8	1.8	378
200	7.5	1.8	417
250	8.3	1.8	461

The table shows that the daily gain increases until the pigs reach about 150 lbs. The amount of feed required per 100 lbs. gain steadily increases as the pigs grow older and fatter. If carried to a heavier weight than 250 lbs., the gain will commonly be less rapid than before, and the efficiency of gain will be considerably lower.

Studies by the United States Department of Agriculture in cooperation with several experiment stations show a very important fact.[3] This is that although the amount of feed required per 100 lbs. gain *during each period* steadily increases, the total amount of feed required per 100 lbs. of *total weight of pigs* decreases until a weight of about 200 lbs. is reached. Up to this time, the increase in feed required per 100 lbs. gain is more than offset by the fact that the large amount of feed needed to produce a pig up to weaning time, is distributed over a greater final live weight.

In this study the following amounts of total feed were required per 100 lbs. weight at the end of each period: To a live weight of 100 lbs., 496 lbs. feed per 100 lbs. of pigs; to a weight of 150 lbs., 459 lbs. feed per 100 lbs. of pigs; to a weight of 200 lbs., 448 lbs. feed per 100 lbs. of pigs; and to a weight of 250 lbs., 450 lbs. feed per 100 lbs. of pigs. These amounts include the feed eaten by the breeding herd, which must be charged to the pigs, and also the feed consumed by the pigs up to weaning time. (**1493**)

Pigs of small, early-maturing type become excessively fat before they reach such heavy weights. They then require much more feed per 100 lbs. of total weight than larger-type pigs.

It is emphasized later that when full use is made of good pasture the amounts of grain and supplements needed per 100 lbs. of gain are considerably less, thus decreasing the cost of pork production. (**1453**)

1380. Weight at which to market pigs.—Under normal conditions, most pigs are marketed in the United States when weighing 225 lbs. or less. This is largely because our consumers have a decided preference for rather small cuts of pork that do not carry too much fat. Pigs that yield such pork therefore command a premium over those that are heavier and fatter, unless there is an unusual demand for lard on the market. At present, we have a surplus of animal fats, instead of a scarcity.

When pigs are carried to heavy weights, the dressing percentage increases, as is shown later. (**1445**) Also, the percentage of edible product in the carcass increases slightly. However, after a weight of 200 to 225 lbs. is reached, more than two-thirds of the additional edible product will be fat, and less than one-third lean meat.[3]

To some extent, the proportion of fat in such heavy pork cuts as loins, hams, and shoulders can be standardized by trimming off the excess fat, which is then processed for lard. However, even the lean meat from over-fat hogs has too much fat to suit most of our consumers.

II. Nutrient Requirements of Swine

1381. Importance of efficient rations.—When swine are improperly fed, they are apt to suffer from severe nutritive deficiencies much more frequently than are cattle, sheep, or horses. One reason for this is because they are fed chiefly on grain in such countries as the United States, and they consume relatively little roughage, except when on pasture. For cattle, sheep, and horses, good roughage can largely and sometimes entirely meet their needs for protein, minerals, and vitamins.

Swine also grow more rapidly than

these other animals, and they produce young when less mature. Their requirements for protein, minerals, and vitamins are consequently increased.

Differing from cattle, sheep, or horses, swine need high-quality protein in their rations. This is because there is little synthesis of good-quality protein in their digestive tracts, such as occurs in the rumen of cattle and sheep and in the caecum and large intestine of horses. (**112**) Similarly, the B-complex vitamins are synthesized in the digestive tracts of swine to a far less extent than in the case of these other animals. Because of these facts, in order to secure good returns from swine, they must be fed rations that fully meet their nutrient needs.

The hundreds of nutrition and feeding experiments conducted during the past score of years have revealed in detail the needs of swine for maximum production. These experiments have proved that it is exceedingly important to provide swine, especially the breeding herd and young pigs, with good pasture whenever possible. When pasture is not available, well-cured alfalfa or other legume hay is the most economical substitute.

The most recent development in increasing the efficiency of pork production is the use of an antibiotic feed supplement to increase the rate of gain and reduce the feed required per 100 lbs. gain by growing and fattening pigs. (**1422**)

The great differences in the results from an inefficient ration and from a modern, complete ration were well shown by a recent Minnesota demonstration with pigs in dry lot.[4] Spring pigs fed an efficient ration from weaning until they reached 200 lbs. in weight, gained an average of 1.81 lbs. a day and required only 291 lbs. corn and 52 lbs. of complete supplement per 100 lbs. gain. Other pigs from the same litters, fed corn, tankage, minerals, and vitamin A-D supplement, but with no alfalfa hay, gained only 1.20 lbs. a day and required 13 per cent more feed per 100 lbs. gain. Still other pigs were fed corn with no protein supplement, but with supplements supplying minerals and vitamins A and D. On this unbalanced ration the pigs made very low gains, only 0.45 lb. a day, and required more than twice as much feed per 100 lbs. gain as did the pigs fed the modern ration.

1382. Feeding standards; digestibility of feeds by swine.—The amounts of dry matter, digestible protein, total digestible nutrients, calcium, phosphorus, and carotene advised per head daily for the various classes of swine are stated in the Morrison feeding standards in Appendix Table III. For those desiring to compute rations according to the net-energy system, net-energy allowances are also given. The standards for growing and fattening pigs are for those that are full-fed, so as to make rapid gains in weight.

These standards are designed for use with the values for digestible nutrients in various feeds that are given in Appendix Table I. Relatively few digestion trials have been conducted with swine, in comparison with the large number that have been carried on with ruminants. It therefore seems wiser to the author to use in computing rations for swine the digestible nutrient values in Appendix Table I, than to use a separate set of values, computed from the limited data obtained in digestion trials with swine.

There is not much difference in the ability of swine and of ruminants to digest concentrates that are not high in fiber.[5] Because of the great difference in the digestive tracts, swine digest a much smaller percentage of the fiber in feed than do cattle or sheep, or even horses.

This difference is not important in the case of most concentrates, for they are relatively low in fiber. However, swine digest hay and other roughages much less completely than do ruminants. It is for this reason, as well as because of the limited capacity of their digestive tracts, that swine are not able to make as much use of roughage as do cattle, sheep, or horses. Pigs have much less ability to utilize roughage than do older swine, such as brood sows.

The Morrison standards are based on studies by the author of the available data concerning the nutrient requirements of the various classes of swine.

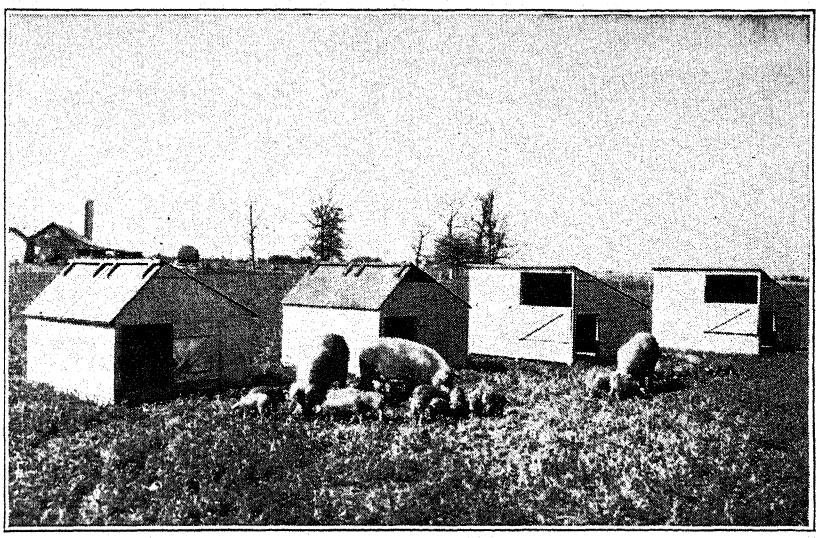
Due consideration has also been given to the feeding standard recommendations that have been made by other scientists,[6] especially to the report made by the special committee of the National Research Council, which has been mentioned previously.[2]

1383. Importance of good pasture or legume hay.—Wherever possible, swine should be provided with good pasture during the growing season and with well-cured legume hay when pasture is not available. These are especially needed for young pigs and for brood sows. Nothing is more important in reducing the cost of pork production and in preventing nutritive deficiencies.

As is explained later, there will generally be no deficiencies of vitamins when swine are fed sufficient well-cured legume hay or when they are on good pasture. (1406)

These feeds also aid greatly in meeting the protein requirements. This is because actively-growing pasture crops and also legume hay are fairly rich in protein, and the protein of these forages is of such kind that it helps to correct the deficiencies in the protein of the cereal grains. Legume hay and legume pasture crops are also very rich in calcium, and other good swine pasture crops supply much more calcium than do any of the grains or the grain by-products.

In addition to these virtues, good pasture amply meets the vitamin needs of swine. Legume hay of excellent quality supplies plenty of carotene, and if it is field-cured it also furnishes vitamin D. Fully as important, good pasture and high-quality legume hay provide B-complex vitamins and certain unidentified vitamins or factors needed by swine. (1415)



GOOD PASTURE PREVENTS NUTRITIVE DEFICIENCIES

Serious nutritive deficiencies may occur when sows are kept continuously in dry lot, even when well-balanced rations are fed. These deficiencies are prevented by good pasture.

Full-fed growing and fattening pigs do not consume a large amount of dry roughage, even of excellent legume hay. Therefore, when pigs are fed liberally on corn or other low-protein grain, they cannot eat enough of such roughage to balance the ration completely in protein content. In order to secure rapid and economical gains, a sufficient amount of an efficient, concentrated protein supplement must hence be added to furnish the proper amount of protein and also to supply protein of excellent quality. (1385–1391)

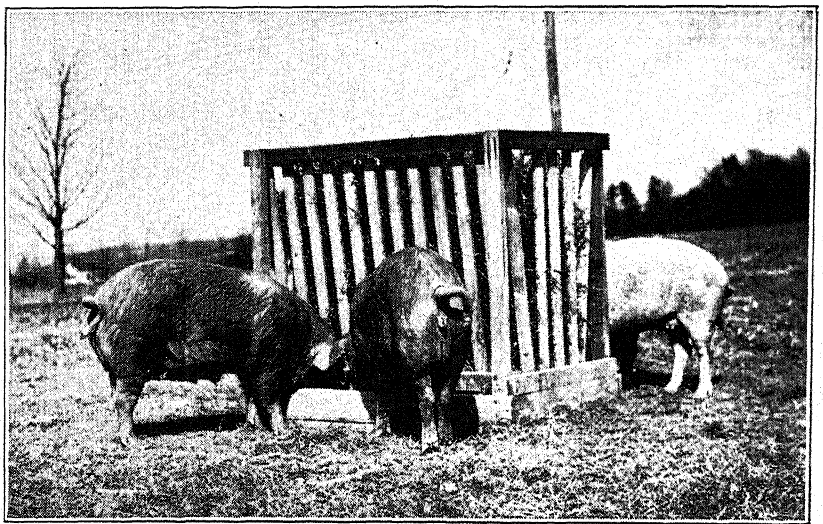
During the growing season, good pasture should be provided for swine, especially for young pigs and for brood sows, because green forage and pasture conditions are definitely superior to legume hay in meeting their nutritive essentials.

1384. Serious deficiencies with continuous dry-lot feeding.—Several investigations have shown that it is hazardous to confine swine continuously to a dry lot, without providing any pasture or other green feed.[7] In these experiments serious nutritive deficiencies have often developed when brood sows have been raised in dry lot and kept there continuously.

This has occurred even when rations were fed that would have been entirely satisfactory for sows which were on pasture part of the year. Many of the pigs from the sows kept continuously in dry lot were born weak or dead. Also, the milk of the sows was so deficient in amount or quality that a large proportion of the pigs born alive did not survive.

Such disaster even occurred when the sows were fed a well-balanced ration of yellow corn, tankage or fish meal, minerals, and 5 per cent of well-cured alfalfa hay or dehydrated alfalfa meal. The trouble is apt to be more serious when no protein supplement of animal origin, such as tankage or fish meal, is included in the ration. Such a supplement furnishes vitamin B_{12}, which is required by swine. (1414)

These deficiencies are entirely prevented by good pasture. Also, increasing the proportion of good alfalfa hay in the ration for sows to 10 to 15 per cent or even more is nearly as effective.



SWINE NOT ON PASTURE SHOULD HAVE LEGUME HAY

Well-cured legume hay provides insurance against lack of vitamins. These sows are provided with good alfalfa hay in the rack. (From J. P. Willman, Cornell University.)

The bad results are apparently due to the lack of certain vitamins. There has been a marked improvement when all the known B-complex vitamins have been added in pure form to the rations. However, increasing the alfalfa hay has been more beneficial than adding the pure B-complex vitamins. This indicates that the injuries are partly produced by a lack of certain unidentified vitamins or factors that are furnished by pasture and by excellent legume hay. These are discussed in a later article, and information is given concerning supplements that provide them. (1415)

Such deficiencies in dry-lot rations for sows are not prevented by adding a vitamin A-D supplement or any complex mineral mixture.

When pigs that are thrifty at birth are raised entirely in dry lot on a good ration, but without pasture at any time, nutritive deficiencies sometimes develop. This may occur even when the pigs are fed such a ration as yellow corn and a trio-type supplemental mixture. (**1418**) Some pigs may become unthrifty and fail to make normal gains, and they may become lame or be unable to walk normally, because of incoordination of movements.

Such troubles can nearly always be prevented by giving the pigs a good start on pasture. Increasing the percentage of first-rate alfalfa hay in the ration to 10 or 15 per cent also usually prevents the deficiencies. (**1417**)

The deficiency troubles with brood sows and pigs confined to dry lot seem to be less apt to occur when a liberal amount of skimmilk is fed. Thus, in an Arkansas experiment satisfactory litters were raised in 2 successive generations by sows confined to dry lot and fed yellow corn and skimmilk, with irradiated yeast as a vitamin D supplement.[8]

1385. Protein of good quality essential.—In swine feeding it is fully as important to provide protein of good quality in the ration as it is to supply a sufficient amount of protein. (**106**) This is especially necessary for young pigs and also for brood sows that are nursing litters.

None of the cereal grains furnishes protein of good quality, and the quality of protein in corn and the grain sorghums is apparently lower than that in wheat, barley, or oats. Skimmilk, other dairy by-products, fish meal, digester tankage, and meat scrap all provide protein that corrects the deficiencies of the protein in the cereal grains. Therefore any one of these feeds of animal origin can be used satisfactorily as the only protein supplement for swine. However, for swine not on pasture, legume hay should be included in the ration to provide vitamins.

It is shown later in this chapter that even better results are secured when pigs not on pasture are fed such a protein supplement as a trio-type mixture than when the only supplement is tankage or meat scrap. (**1418–1419**) Likewise, even for pigs on pasture certain combinations of tankage and protein supplements of plant origin may be more efficient or more economical than tankage as the only supplement to grain. (**1421**)

It has been emphasized in Chapter XXII that soybean oil meal which has been properly cooked in the manufacturing process is an excellent protein supplement for swine. (**805**) For swine on good pasture it is satisfactory as the only protein supplement, if a mineral mixture is supplied that furnishes calcium and phosphorus. For swine in dry-lot, legume hay should be included in the ration, as advised previously. Even better results are secured when soybean oil meal is used in one of the efficient protein supplements described later.

Peanut oil meal which is low in fiber ranks close to soybean oil meal as a protein supplement for swine, and may be used similarly. Peanuts and cooked soybeans also correct the deficiencies in the protein of the grains. However, both of these feeds produce soft pork when too much is included in the ration. (**1446–1447**)

Part of the protein needed to balance a ration for swine may be provided by a protein supplement that would not be satisfactory if used as the only supplement to cereal grains. For example, linseed meal or wheat middlings are very inefficient when used as the only protein supplement to corn for pigs in dry lot. However, when one of these supplements is used in combination with a limited amount of tankage, fish meal, or dairy by-products, excellent results are produced.

The value and use in swine feeding of the various protein supplements are discussed in detail in the chapters of Part II.

1386. Certain feeds unsatisfactory as only supplements.—Any ration made up of only corn or grain sorghum and grain by-products is very unsatisfactory

for pigs, even when a mineral mixture is supplied to furnish plenty of calcium and phosphorus and when there is no lack of vitamins A or D. For example, if pigs are fed yellow corn supplemented by wheat middlings, corn gluten feed, corn gluten meal, rye feed, brewers' dried grains, or distillers dried grains, they will make poor and expensive gains, even if they are out in the sunlight (which will supply vitamin D) and if they are fed a suitable mineral mixture to provide additional calcium and phosphorus.

The results will still be poor if the pigs are fed a mixture of corn and other grains supplemented by a combination of two or more of these protein-rich grain by-products. Thus, a combination of corn, barley, oats, wheat middlings, and corn gluten meal furnishes protein of unsatisfactory quality for swine.

Linseed meal is no more effective than wheat middlings as the only protein supplement to corn in swine feeding. Likewise, none of the following produces good results when used as the sole protein supplement to corn in swine feeding: Cottonseed meal, field peas, cowpeas, field beans, coconut meal, or buckwheat middlings. If the pigs are fed choice legume hay in addition to corn, these protein supplements will produce better results than without the legume hay. However, especially in the case of young pigs, the gains will be much more rapid and economical if these supplements are combined with such supplements of animal origin as tankage, fish meal, or dairy by-products.

Excellent pasture, like alfalfa, clover, or rape, furnishes a considerable amount of protein of good quality. On excellent pasture, even young pigs make fairly good gains on a ration consisting of corn, a suitable mineral mixture, and such a protein supplement as linseed meal or wheat middlings. However, it generally pays to include a more efficient protein supplement in the ration.

Experiments have shown that linseed meal or field peas are more satisfactory as the only protein supplement to barley or wheat for pigs in dry lot, than as the only protein supplement to corn. (835, 855) This shows that better quality protein is provided by the combination of wheat or barley with one of these supplements than by the combination of corn with the same supplement.

1387. Amounts of protein required.—Because of their rapid growth, pigs need rations containing liberal proportions of protein. Unless care is taken to meet this requirement, they will make slow and expensive gains.

Young pigs require a much greater proportion of protein than do those which are older and are therefore storing less protein and more fat in their bodies. (259) Often this fundamental fact is overlooked, and pigs are fed the same proportion of protein supplement from weaning time to market. If there is enough protein supplement in the mixture to produce good growth when the pigs are young, there will be considerably more than is needed after they reach weights of 100 to 125 lbs. On the other hand, if only a small proportion of supplement is used throughout the entire period, the pigs will have too little protein while they are young to make rapid and efficient gains.

Several recent experiments have proved that if a ration furnishes ample minerals and vitamins, growing and fattening pigs need considerably less protein to produce rapid and efficient gains than was formerly thought necessary.[9] The greater gains of the pigs on higher levels of protein in the earlier experiments seem to have been due to the larger amounts of B-complex vitamins provided by the high-protein rations, rather than to more protein itself.

The amounts of digestible protein recommended in the revised feeding standards for growing and fattening pigs in Appendix Table III are based upon the results of these recent experiments.

The protein requirements of brood sows during pregnancy and during lactation are discussed in the next chapter. (1456)

1388. Percentages of total protein needed in swine rations.—Swine are often fed a mixture of ground grain with the proper proportion of protein supple-

ments and also mineral and vitamin supplements. In making up such mixtures it is therefore convenient to know the percentage of total protein (not digestible protein) needed in the entire ration.

The special committee of the National Research Council has recommended, in its report on "Nutrient Requirements of Swine," that rations for growing and fattening pigs should have the following percentages of total protein: At a weight of 25 lbs., 18 per cent; at 50 lbs., 16 per cent; at 100 lbs., 14 per cent; at 150 lbs., 13 per cent; at 200 lbs. and above, 12.0 per cent.[2]

For pregnant females and breeding boars the committee has recommended a total protein content of 15 per cent for young stock and 14 per cent for adults. For lactating sows the recommended percentages are 15 per cent for gilts and 14 per cent for adult sows.

Swine on alfalfa or other protein-rich pasture of course need less protein in the concentrate mixture than do those in dry lot. The proportions of protein supplements required on pasture are indicated in the example rations given in Appendix Table VII.

In the recent experiments on protein requirements of growing and fattening pigs, which have been mentioned previously, sometimes rapid and efficient gains have been made on rations containing even less protein than advised by the committee. However, low levels of protein tend to produce more fat and less lean in the carcass. This is undesirable from the standpoint of the preference of our consumers for leaner pork cuts.

The protein requirements of swine are actually chiefly requirements for sufficient amounts of the various essential amino acids, rather than a need for a certain amount of protein. Therefore a lower percentage of protein will produce good results when the protein is of excellent quality. For example, in an Illinois experiment weanling pigs made rapid gains on a ration having only 10.2 per cent protein, in which dried skimmilk furnished practically all the protein.[10]

When protein supplements are unusually high in price in comparison with the cost of grain, it may be most economical to feed a smaller amount of supplement than is needed to produce the most rapid gains.[11] The law of diminishing returns applies here, as it does in many phases of animal husbandry. (**1025**) When added to a concentrate mixture that has just enough protein to keep pigs thrifty, each additional pound of protein supplement added successively to the mixture will have a lower value than the previous pound. Finally, when the mixture has sufficient protein to produce maximum gains, any additional amount of protein supplement will be worth no more per pound than farm grain. (**815**, Appendix Table II)

Catron of the Iowa Station has developed a convenient slide rule for finding the most economical proportion of soybean oil meal and corn for feeding pigs of various weights, with these feeds at different prices.[12]

1389. Amino acid requirements.—The approximate percentages of all of the 10 essential amino acids required in a ration for weanling pigs have been determined in recent careful experiments.[13] In these experiments various amounts of the amino acid being studied were added to a highly purified diet which was deficient in that amino acid. A very limited amount of such information has been thus obtained concerning

Amino acid requirements of weanling pigs

Amino acid	Percentage of total ration
L-Arginine [1]	0.20
L-Histidine	0.20
L-Isoleucine	0.70
L-Leucine	0.60
L-Lysine	1.00
DL-Methionine [2]	0.22
DL-Phenylalanine	0.46
L-Threonine	0.40
DL-Tryptophan	0.20
L-Valine	0.40

1 This level is adequate but the minimum requirement has not been determined.

2 This percentage of methionine is ample when a ration has the usual amount of cystine, which can partially replace methionine.

the amino acid requirements of baby pigs.[14] Similar investigations have not been conducted with well-grown pigs.

The preceding table states the approximate amounts of the different essential amino acids needed for growth by weanling pigs.

The percentage of protein needed in the diet for baby pigs is higher than for weanling pigs, and also the percentages of the essential amino acids.

1390. Correcting amino acid deficiencies.—Several experiments have been conducted recently with weanling pigs to find whether there were any amino acid deficiencies in certain practical rations.[15] In these studies the effect was determined of adding definite small amounts of the amino acid or amino acids that might possibly be deficient in the ration being tested.

From these studies and other data, especially the information concerning the percentages of the essential amino acids, given in Appendix Tables VIIIa and VIIIb, certain conclusions can be drawn. It must be borne in mind that the data concerning the minimum requirements for the essential amino acids are still limited, and that such tables as Appendix Tables VIIIa and VIIIb can show only the approximate content of the amino acids in various feeds.

First of all, the available data indicate there is not apt to be a deficiency of any amino acid in a ration where the protein comes from 3 or more good sources, and where a considerable part is supplied by such feeds as soybean oil meal, fish meal, or dairy by-products. This is especially true when alfalfa hay or alfalfa meal is included in rations for pigs not on pasture.

A ration in which all the protein is furnished by corn grain and meat scrap or tankage is decidedly deficient in tryptophan for young pigs. This is shown by the fact that a combination of 84 lbs. corn (Grade No. 2) and 16 lbs. meat scrap (55 per cent protein grade) will have 16 per cent protein, thus meeting the total protein requirement of weanling pigs. However, the corn-meat scrap mixture will have only about one-half as much tryptophan as young pigs need.

The required amount of tryptophan could be supplied by adding the pure amino acid, but it is far too expensive to be used in a practical ration. Therefore some natural protein supplement which is rich in tryptophan should replace part of the meat scrap.

Soybean oil meal, wheat standard middlings or shorts, and alfalfa hay or meal all have twice as much tryptophan, per pound of protein, as does meat scrap. (Appendix Table VIIIb.) Including sufficient amounts of these feeds in the ration will hence correct the tryptophan deficiency.

A ration of corn, meat scrap, soybean oil meal, and alfalfa will often furnish a little less methionine than the requirement stated in the preceding table. However, as shown later in this chapter, such a ration produces excellent results with young pigs, without any addition of methionine. (**1418**)

A ration in which corn and low-gossypol cottonseed meal furnish all the protein is somewhat low in lysine and also in methionine for young pigs. It will be greatly improved by substituting soybean oil meal, meat scrap, tankage, fish meal, or fish solubles for part of the cottonseed meal. Further improvement will be made by including alfalfa for pigs not on pasture. The protein in all these feeds has much more lysine than there is in cottonseed meal protein.

The results of the experiments have differed in which pure amino acids have been added to rations in which all of the protein has come from corn and soybean oil meal. In some trials adding lysine or methionine has been beneficial, but not in other tests. However, as is pointed out in Chapter XXII and also later in this chapter, the best results for young pigs in dry lot are usually secured when soybean oil meal is combined with such a supplement as meat scrap, tankage, or fish meal.

Milo and possibly other grain sorghums are even lower than corn in lysine. Therefore it is especially important to correct this lack by protein supplements rich in this amino acid.

As pointed out in Chapter V, methionine is the only pure amino acid yet available at a low enough price to warrant its use in practical rations. (128) Adding 1 lb. of methionine per ton to a formula feed would increase the methionine content 0.05 per cent at a cost of not over $3.00 per ton.

1391. Self-feeding protein supplements free-choice.—Pigs show a remarkable ability to balance their rations in protein when they are self-fed corn or other low-protein grains and also self-fed separately *certain* single protein supplements or *certain* supplemental mixtures. At early ages they eat enough of such a supplement to balance their ration, and then gradually eat a smaller proportion of supplement as they grow older and their need for protein is less.

This free-choice plan usually works excellently with pigs on pasture or in dry lot fed tankage, meat scrap, or fish meal as a single supplement to corn or sorghum grain, or when a trio mixture or a similar combination is self-fed with these grains. (**1418–1420**)

Occasionally, the pigs may eat somewhat more supplement than they need, and once in a while they may not consume as much of the supplement as they should. However, the results from the free-choice method of feeding these supplements with corn will average fully as good or better than when time is taken to mix the proper proportion of supplement with ground corn or to hand-feed the supplement.

The free-choice plan of self-feeding grain and protein supplement is not so well suited for use with barley, oats, or rye. With these grains less protein supplement is needed than with corn, for they contain somewhat more protein. However, the pigs often eat fully as much of the supplement as when they are self-fed corn. To avoid wastage of the protein supplement it is therefore necessary to mix the proper proportion of the supplement with the ground grain, or else to hand-feed the amount of supplement that is actually needed to balance the ration. Wheat is so palatable to pigs that they generally do not eat more than they need of such a protein supplement as tankage or fish meal, when they are self-fed wheat and the supplement, free-choice.

When pigs are self-fed, free-choice, corn and certain protein supplements or supplemental mixtures, they are apt to eat much more of the supplement than they need, especially if they are on good pasture. This may occur with soybean oil meal or with such a mixture as one-half soybean oil meal and one-half meat scrap or fish meal.

In such a case, ground legume hay, salt, or mineral supplement can be mixed with the protein supplement in a proportion that will make the correct reduction in the amount eaten. Another way of preventing waste of protein supplement is to hand-feed just enough to balance the ration.

1392. Protein supplement needed in dry-lot.—Many experiments years ago proved that growing and fattening pigs in dry lot cannot make satisfactory gains or even remain thrifty on grain alone, without a protein supplement. Even when grain is fed with a mineral supplement, but without additional protein, the gains are slow and expensive. Sometimes the pigs will become runts or even die because of the inadequate ration.

Balancing the ration by the addition of a good supplement will double the rate of gain in the case of young pigs. Also, each 100 lbs. of protein supplement will save 500 to 600 lbs. or more of corn, without considering the advantage of the more rapid gains.

After pigs in dry lot have reached a weight of 175 to 200 lbs., they may make fair gains on corn without a protein supplement, because their requirements for protein are then not high. However, the gains are usually much more rapid and also somewhat more economical when the use of a good supplement is continued until the pigs are marketed.[16]

On barley, wheat, or oats as the only feeds, or on these grains plus a mineral supplement, the gains may be somewhat better than on corn, because these grains supply more protein and protein of somewhat better quality than does

corn. However, in the case of pigs not on pasture, the gains are greatly increased by the addition of a sufficient amount of a good protein supplement to balance the ration.

Adding alfalfa hay or other legume hay to corn for pigs not on pasture will generally permit fair gains and prevent serious nutritional trouble. However, as has been shown in Chapter XVI, the gains on only corn and alfalfa hay are much less rapid and usually more expensive than when such a supplement as tankage or soybean oil meal is also fed. (464)

Because barley, wheat, and oats are higher than corn in protein, the results are somewhat better when alfalfa hay is fed as the only supplement to these grains. However, unless tankage and other efficient protein supplements are unusually high in price, it generally pays to add a limited amount of such a supplement to a ration of any of these grains and good-quality alfalfa hay, especially for pigs under 100 to 125 lbs. in weight.[17]

1393. Feeding a protein supplement on pasture.—When pigs are on first-class pasture, considerable protein and protein of fairly-good quality is provided by the green forage they eat. Pigs will therefore make fair gains when full-fed corn on such pasture, without any protein supplement, especially if a mineral mixture is provided to furnish plenty of calcium and phosphorus.

However, pigs will not eat enough pasturage in addition to a full feed of corn to balance their ration completely. The rate of gain will therefore be considerably increased by adding an efficient protein supplement. Nevertheless, each 100 lbs. of the supplement will save a much smaller amount of corn than when fed to pigs not on pasture.

In the case of early spring pigs, the increase in the rate of gain produced by the supplement is more important than the saving of corn. If such pigs are full-fed on corn plus a good supplement, they can be brought to market weights before the severe slump in hog prices which usually occurs in late autumn. (1427) On the other hand, if no supplement is fed it will take at least 2 to 4 weeks longer to get them to the same weights, and during this time the price may decline 50 cents or more per hundredweight. Because of the difference in selling price, it will usually be most profitable to feed a supplement if pigs can thereby be hurried to market early in the fall.

Whether or not to feed a supplement to later pigs will depend on the age of the pigs, on the rate of gain that is desired, and on the relative price of corn and of supplements. Except when supplements are high in price in comparison with corn, it is probably best to feed a supplement until the pigs reach a weight of at least 100 lbs.

Because Ladino clover pasture is especially rich in protein and also very palatable to pigs, there is less advantage from feeding a protein supplement than with pigs on most other pastures.[18]

Unless the pasture is excellent, good gains cannot be secured without a supplement. Thus, there is more advantage in feeding a supplement to pigs on grass pasture (such as bluegrass, timothy, or Sudan grass) than to pigs on excellent legume or rape pasture.[19]

The benefits from using tankage or some other efficient supplement for pigs full-fed corn on good pasture and also supplied with a mineral mixture, are shown by the results of 23 experiments.[20] In these trials pigs which averaged 64 lbs. in weight at the start were full-fed corn up to market weights on legume or rape pasture, and in addition were provided with a mineral mixture that supplied calcium and phosphorus.

The pigs fed tankage or another efficient supplement gained an average of 1.53 lbs. per head daily and required only 310 lbs. corn, 26 lbs. tankage or tankage equivalent, and 3 lbs. mineral mixture per 100 lbs. gain. Those fed no protein supplement gained 1.32 lbs. per head daily and required 352 lbs. corn, 4 lbs. mineral mixture, and 0.5 lb. tankage equivalent per 100 lbs. gain. (In a few trials the pasture became exhausted a few days before the pigs were ready for market. A protein supplement was

then fed to the pigs which had received no supplement previously.)

In these experiments each 100 lbs. of tankage or tankage equivalent saved only 161 lbs. corn plus 4 lbs. of mineral mixture, if no value is placed on the difference in rate of gain. The pigs fed the protein supplement also undoubtedly ate a little less pasturage.

If no mineral mixture is provided for pigs full-fed corn on good pasture, there is a somewhat greater advantage in adding a protein supplement. For example, adding tankage to this ration for pigs averaging 60 lbs. in weight at the start increased the daily gain from 1.13 lbs. to 1.46 lbs., on the average, in 27 experiments.[21] In these numerous trials each 100 lbs. of tankage saved an average of 282 lbs. corn, not considering the difference in rate of gain.

Experiments have shown that for pigs on good pasture that are fed barley, wheat, oats, or rye (which contain more protein than does corn) there is less benefit from adding a protein supplement.[22] After pigs fed these grains reach a weight of about 100 lbs., it does not usually pay to add a supplement, unless maximum gains are desired. Up to this weight, it is generally best to feed a small amount of supplement, unless the pasture is unusually good or protein supplements are high in price. With these grains, pigs on pasture will often eat too much of the supplement if it is self-fed, free-choice. The proper proportion should therefore be mixed with the ground grain, or a small amount of the supplement should be hand-fed daily.

EXCELLENT PASTURE BALANCES THE RATION

After pigs reach a weight of 100 to 125 lbs. they make good gains when fed only corn and a mineral supplement on excellent pasture, such as this alfalfa pasture.

When the pasture is good, 4 lbs. of tankage or fish meal of usual grades are enough per 100 lbs. of these grains for pigs under 100 lbs. in weight. If a supplement is fed to older pigs, not over 2 to 3 lbs. of tankage or fish meal per 100 lbs. of grain are advisable. When the supplement is hand-fed to pigs getting barley, oats, wheat, or rye on good pasture, 0.2 lb. per head daily of tankage or fish meal is sufficient.

If pigs are fed only a limited amount of grain on good pasture, they will eat more of the green forage than when full-fed on grain. There will therefore be less benefit from adding a protein

supplement to the ration, and under usual conditions it will not pay to use a supplement, even when the grain is corn.[23]

1394. Feeding no protein supplement to well-grown pigs.—For pigs on good pasture, most of the advantage from feeding a supplement to corn and minerals can be gained by using the supplement only until the pigs reach a weight of 100 to 125 lbs. Unless one wishes to get early spring pigs to market before the price drops in the fall, this method will usually be more economical than to feed the supplement until the pigs are marketed.

In 6 experiments pigs on good pasture gained an average of 1.59 lbs. a day when fed a protein supplement to corn and minerals only up to a weight of 100 to 125 lbs., and then fed only corn and minerals.[24] When the supplement was fed until the pigs were ready for market, the average daily gain was 1.72 lbs. The average cost of feed per 100 lbs. gain was 31 cents less when no protein supplement was fed during the final period. In these trials each 100 lbs. of protein supplement that was fed after the pigs reached a weight of 100 to 125 lbs., saved only 95 lbs. corn and 5 lbs. of mineral mixture.

1395. Fat; addition of fat to rations.—Normal rations of grain and protein supplements will always supply enough fat for efficient gains by growing and fattening pigs, even when the chief protein supplement is a solvent-process oil meal. While the minimum fat content of practical rations is therefore not important, soft pork is produced if the ration has too large a percentage of a kind of fat which produces soft body fat. The extent to which such softening feeds as soybeans or peanuts can be fed without producing soft pork is discussed later in this chapter. (**1446–1447**)

Pigs fed experimental rations containing but 0.5 per cent of fat made satisfactory gains and stored a normal amount of body fat.[25] This is far less than there is in any practical ration. However, pigs apparently require a certain very small amount of fat. (**133**) In Indiana experiments when young pigs were fed highly-purified rations having only 0.06 to 0.12 per cent of fat, characteristic symptoms of fat deficiency developed.[26] These included unthriftiness, scaly, dandruff-like dermatitis, and necrotic areas on the skin. Adding only 1.5 per cent of corn oil to the ration brought recovery.

Because of the low price of surplus by-product animal fats during recent years in this country, experiments have been carried on to find the effects of adding such fats to ordinary rations for growing and fattening pigs.[27] Adding up to 10 per cent of such grease or tallow to the ration has slightly increased the gain in some trials, but not in others. Such a fat addition tends to increase the proportion of fat in the carcass, which is undesirable.

Adding fat to the ration may decrease slightly the amount of feed required per 100 lbs. gain, because of the high energy value of fat. Whether the addition will be economical depends on the price of such fat in comparison with the cost of grain.

The firmness of the fat in the carcass is increased by adding tallow to the ration, but adding grease has the opposite effect.

1396. Total digestible nutrients; fiber.—Swine have only limited capacity to consume roughage, and they do not digest the fiber of feeds well. Consequently, to produce rapid gains the rations of growing and fattening pigs must consist chiefly of grain and other concentrates. Because brood sows have more capacious digestive tracts, they can utilize a somewhat larger proportion of such excellent roughage as alfalfa hay. (**1460**)

The total digestible nutrient requirements and also the desirable amounts of dry matter for swine of various classes are shown in the Morrison feeding standards. (Appendix Table III.)

Growing and fattening pigs usually make the most rapid gains and require the least feed per 100 lbs. gain when their rations do not contain more than about 5 to 6 per cent of fiber.[28] It is therefore not generally economical to use rations having a higher percentage of

fiber for such pigs, unless the prices of corn, barley, wheat, or other feeds low in fiber are very high in comparison with the prices of feeds higher in fiber, such as oats or legume hay.

This is shown by the experiments in which oats have been compared with corn for growing and fattening pigs. It has been shown in Chapter XX that when ground oats do not form more than one-fourth of the ration for pigs in dry lot, oats are worth about as much as corn per 100 lbs. (**725**) On the other hand, when oats are fed as the only grain, they are worth only 79 per cent as much as corn.

Reducing the net-energy intake of pigs, especially during the last third of the growing and fattening period, will produce leaner carcasses than full-feeding a concentrated ration. This is important where a considerable premium is paid, as in Canada, for pigs that yield high-quality bacon carcasses.

The energy intake can be restricted by hand-feeding only enough of the concentrate mixture to produce the desired rate of gain. However, when this is done, the greediest pigs may get more than their share, and consequently become too fat. As is pointed out later in this chapter, the energy supply to all of the pigs can be restricted more uniformly by including in the concentrate mixture a sufficient amount of some feed that is high in fiber, but still is nutritious. (**1431**)

It is emphasized elsewhere in this chapter that it is important to include alfalfa or other legume hay in the rations for swine not on pasture, especially for brood sows and for young pigs. (**1383, 1417**) Except possibly when legume hay is very cheap in comparison with grain, the desirable proportion of legume hay for growing and fattening pigs is from 5 to 15 per cent, depending on the danger of vitamin deficiencies in the ration. The proportion of legume hay for brood sows can be higher, as shown in the next chapter. (**1460**)

Recent Nevada experiments have been conducted to find how much very early-cut, excellent-quality alfalfa hay, having not over 25 per cent fiber, could be satisfactorily included in rations for growing and fattening pigs.[29] Young pigs were early accustomed to a considerable proportion of such alfalfa by including 25 per cent in the creep-fed mixture. This apparently enlarged the capacity of the digestive tract for roughage.

From weaning time to market, pigs made fair gains on rations having as much as 50 per cent of the unusually good alfalfa hay. In 2 trials pigs gained 1.10 lbs. per head daily on such a ration, in comparison with 1.45 lbs. gain made by pigs fed a normal ration. On the high-alfalfa ration 20 per cent more feed was required per 100 lbs. gain.

1397. Minerals.—It is shown in the following articles that the minerals which commonly need consideration in swine feeding are salt, calcium, and phosphorus. In iodine-deficient areas, brood sows need iodized salt or some other iodine supplement to prevent hairless pigs. To avoid anemia when suckling pigs are confined without access to pasture or soil, traces of iron and copper must be supplied by such a method as is described later.

The addition of trace minerals to rations has been discussed in Chapter VI and further information is given later in this chapter. (**1404**)

1398. Salt.—Although swine need less salt than do cattle, horses, or sheep, they should be supplied with it regularly, unless the feeds in the ration furnish enough. The best plan is to let them have access to salt in a suitable box or trough. When salt is thus fed, pigs will eat as much as 0.3 ounce per head daily.

Swine are apt to eat less block salt than flake salt. When block salt is used, it is best to include 20 per cent of salt in the calcium-phosphorus mineral mixture, if such a mixture is also provided. When salt is mixed with the entire ration, not over one-half pound of salt should be added to each 100 lbs. of feed. If pigs have not had salt for some time, they may at first eat too much if given free access to it.

When tankage, meat scrap, or fish meal is fed as the only or the chief protein supplement, there may be little or

no benefit from supplying additional salt, because of the salt these feeds normally contain.[30] On the other hand, it is very necessary to provide salt for swine fed a ration made up wholly or almost entirely of feeds which are of plant origin.

The great benefit from adding salt to such rations is well shown by recent Indiana and Wisconsin trials.[31] In 2 Indiana experiments pigs made an average daily gain of only 0.86 lb. and required 562 lbs. of feed per 100 lbs. gain when fed yellow corn, soybean oil meal, and a mineral mixture containing no salt. Other pigs supplied salt in addition gained 1.61 lbs. and needed only 363 lbs. of feed per 100 lbs. gain. The benefit from supplying salt was somewhat less in a similar Wisconsin test.

From Wisconsin experiments it was concluded that rations for growing and fattening pigs should have 0.08 to 0.10 per cent sodium and 0.12 to 0.13 per cent chlorine.[32] Though the requirement for chlorine is apparently slightly higher than for sodium, the chief deficiency in a ration of grain with plant protein supplements is sodium, rather than chlorine. This is because the grains contain considerably more chlorine than they do sodium.

Salt poisoning of pigs may occur if pigs have access to brine or unusually salty whey, with no other water available.[33]

1399. Calcium.—With the exception of salt, calcium is the mineral nutrient that is most apt to be lacking in swine rations. This is because all the grains and their by-products and also practically all protein-rich concentrates of plant origin are low in calcium. Fortunately, tankage, meat scrap, fish meal, skimmilk, buttermilk, legume forage (pasturage and hay), and rape forage all are rich in calcium. Whether or not there will be any need of supplying swine with a calcium supplement will therefore depend entirely on the ration that is fed.

In experiments at the Kansas Station with growing and fattening pigs, a calcium content of 0.45 to 0.50 per cent in the entire ration on the air-dry basis was sufficient when the ration had ample phosphorus and when the pigs were exposed to sunlight, so there was no deficiency of vitamin D.[34] In similar Wisconsin trials a calcium content of only 0.32 to 0.41 per cent was enough to prevent any symptoms of deficiency.[35] In Missouri studies it was concluded that the rations of brood sows should have at least 0.40 per cent of calcium.[36]

From the results of these and other experiments Bohstedt of the Wisconsin Station concluded that when swine have access to outdoor lots, so they have exposure to sunlight, growing and fattening pigs need no more than 0.45 per cent calcium and breeding stock 0.50 per cent.[37] The author has based the calcium allowances for swine in the feeding standards in Appendix Table III mainly on these conclusions.

Somewhat higher allowances have been recommended in the report of the special committee of the National Research Council which has been mentioned previously,[2] and also in a report from the Iowa Station.[38] The author has not placed his recommendations at these higher levels, because there seems to be no experimental evidence of any calcium deficiency occurring on the levels stated by Bohstedt.

The Wisconsin experiments show that it decreases the gains and the feed efficiency if too much calcium is added to a ration. Also, too much calcium tends to cause parakeratosis in pigs. (181)

The proportion or ratio between the amounts of calcium and of phosphorus is important in rations for swine. (152) From his and other experiments Bohstedt concludes that the calcium-phosphorus ratio should be between 1.1:1 to 1.5:1. In other words, there should be 1.1 to 1.5 parts of calcium to each part of phosphorus.

There will usually be no lack of calcium when swine are fed sufficient tankage, meat scrap, or fish meal to balance their rations. On the other hand, a calcium supplement is essential when corn or other grain is fed with a protein supplement low in calcium, such as soybean oil meal, linseed meal, or wheat

middlings. This is especially important for pigs not on pasture.

There is not likely to be a lack of calcium when swine are on legume or rape pasture, even when fed grain and a protein supplement low in calcium. However, pigs hogging down peanuts need a calcium supplement to prevent a serious lack of the mineral.[39] Ohio experiments indicate that for pigs not on pasture a ration of corn supplemented by the usual amount of skimmilk may not supply quite enough calcium for the best results with young pigs.[40]

1400. Phosphorus.—There is much less apt to be a lack of phosphorus in swine rations than of calcium, because most protein-rich supplements are rich in phosphorus. Also, though the cereal grains are not rich in phosphorus, they contain much more phosphorus than calcium. Tankage, meat scrap, and fish meal are especially rich in this mineral, and skimmilk, buttermilk, and wheat middlings, wheat bran, linseed meal, and cottonseed meal are also high in phosphorus. Soybeans, soybean oil meal, and peanut oil meal contain considerably more than do the cereal grains.

In Kansas and Illinois experiments a phosphorus content of 0.27 to 0.30 per cent on the air-dry basis was sufficient in rations for growing and fattening pigs which had ample calcium and when there was no lack of vitamin D.[41]

Bohstedt of the Wisconsin Station concludes from the results of his and various other experiments that in the case of swine with some exposure to sunlight by access to outside lots, 0.33 per cent of phosphorus is adequate for growing and fattening pigs and 0.40 per cent for breeding swine.[37]

The author has followed these recommendations in the main in the allowances of phosphorus stated in Appendix Table III, instead of higher levels stated in the report of the special committee of the National Research Council [2] or in a recent report from the Iowa Station.[38] He has done this because no phosphorus deficiency has been reported when swine, handled under practical conditions, have received only as much phosphorus as recommended by Bohstedt.

If swine have no exposure to sunlight and are fed a ration deficient in vitamin D, there should be a somewhat higher level of phosphorus in the ration.[42] However, this is not a practical way to feed swine.

Indiana and Iowa experiments show that phytin phosphorus, which forms a considerable part of the phosphorus in many feeds of plant origin, is not quite so well utilized by pigs, as is phosphate phosphorus, such as in bone meal or mineral phosphorus supplements.[43] (**151**) However, pigs apparently utilize phytin phosphorus much better than do poultry. In Wisconsin experiments growth, fattening, and reproduction were satisfactory on rations in which all the phosphorus came from grain and other plant sources, and the phosphorus level was no higher than previously stated.

Several experiments have shown that when corn or other grain is supplemented chiefly or entirely with soybean oil meal or soybeans, a mineral supplement should be added that furnishes both calcium and phosphorus.[44] The chief mineral deficiency in such a ration is calcium. However, the addition of ground limestone or another calcium supplement does not produce as good results as the use of bone meal or a combination of limestone and bone meal.

The various phosphorus supplements have been discussed in Chapter VI. (**158–169**) For continued feeding, a phosphorus supplement having a dangerous amount of fluorine should not be used as the chief source of phosphorus. When added to a phosphorus-deficient ration for pigs, soft phosphate with colloidal clay (colloidal phosphate) has in some trials produced less rapid growth than bone meal or dicalcium phosphate.[43] In an Iowa trial colloidal phosphate produced weaker bones than the other phosphorus supplements. In an Indiana experiment it caused pitting and decay of the molar teeth, because of the high content of fluorine.

1401. Adding calcium or phosphorus supplements.—Numerous experi-

ments have proved that there is generally no decided advantage in adding a calcium or phosphorus supplement to a well-balanced swine ration consisting of grain with tankage, meat scrap, fish meal, or skimmilk as the chief supplement.[45] In some cases, pigs have made slightly more rapid or economical gains when fed the mineral supplements in addition to salt, but in other tests there has been no benefit whatsoever from the calcium or phosphorus supplements. Similar results have been secured in experiments with brood sows and with gilts being raised for the breeding herd.

Since there has been a slight benefit from these mineral supplements in some cases, it may be wise to provide a suitable mineral mixture where swine can have access to it, even when they are fed such good rations. However, it should be understood that on these rations excellent results will be secured without the calcium and phosphorus supplements, and often there will be no advantage from their use.

There is more apt to be a slight benefit from the addition of mineral supplements to efficient rations for swine that are not on good pasture. Also, there is probably more advantage from providing such mineral supplements for brood sows and for young pigs fed good rations than for fattening pigs.

When there is a definite lack of calcium or phosphorus in the ration, then the mineral need must be met, or unsatisfactory results will be secured.[46] If the lack is pronounced, rickets will be caused and disaster may follow. Brood sows suffering from a serious deficiency of either of these minerals are unable to produce thrifty offspring. Many pigs will be born dead or weak, and the sows may be unable to provide an adequate supply of milk for those that appear normal at birth.

A supplement such as bone meal, which furnishes both phosphorus and calcium, should be provided when pigs on pasture are fed only corn or other grain, without any protein-rich concentrate, or when pigs in dry lot are fed only corn or grain sorghum with alfalfa or other legume hay.[47] A mineral supplement is less advantageous in the case of barley, wheat, or rye, as these grains contain somewhat more of these minerals.[48]

A good method of supplying a mineral supplement is to let the swine have access to a suitable mineral mixture in a box or self-feeder, so they can take as much as they desire. (186) Experiments have shown that it is unwise to mix with the concentrates a considerably greater amount of mineral supplement than is actually needed.

For example, in Texas trials pigs did better when 1 per cent of ground limestone was added to corn supplemented with a plant-protein supplement than when more limestone was added.[49] Similarly, in Wisconsin tests 1 per cent of bone meal or equal parts of ground limestone and bone meal gave better results than a larger amount of mineral supplement, when added to corn and soybean oil meal.[50]

It has been pointed out previously in this chapter that in swine rations it is important to have a proper calcium-phosphorus ratio. (1399)

1402. Iodine; prevention of goiter or hairlessness in pigs.—In regions where there has been trouble from goiter in new-born pigs, or so-called "hairless pigs," it can readily be prevented by supplying the brood sows with iodized salt instead of ordinary salt, during at least the last 12 weeks of pregnancy. (170) Even in border-line areas where there are rarely definite cases of hairlessness in new-born pigs, there may be a decided benefit from supplying the sows with iodized salt. (171)

In areas where there is definite lack of iodine and frequent cases of goiter in livestock, it is probably wise to use iodized stock salt instead of common salt for brood sows throughout the year and also to use this salt for growing and fattening pigs. On the other hand, there is no benefit from using iodized salt in areas where there is no deficiency of iodine.[51]

1403. Anemia in suckling pigs.—It has been explained in Chapter VI that

if suckling pigs are kept in pens or paved lots, away from contact with soil or sod, serious losses will often occur from anemia (lack of red blood cells) caused by a deficiency of iron and copper, unless special precautions are taken. (**174**) If the young pigs have access to pasture or even to the soil in an exercise plot, they begin to eat forage or to nibble at lumps of dirt within a few days after birth and thus get the exceedingly small amounts of these minerals necessary to prevent anemia.

When they do not have access to pasture or dirt, however, the number of red blood cells and the amount of hemoglobin in the blood decline rapidly, and often death results at from 3 to 6 weeks of age. In white pigs the anemic condition is clearly visible in the lack of a healthy pink color of such parts as the ears and nose. Anemic pigs usually have little appetite, are weak and inactive, and in severe cases breathe in the labored manner commonly described as "thumps." If they survive for 6 weeks, they usually recover from the anemia, because they then eat considerable food other than milk. However, pigs that have had anemia generally do not make good gains for a period of several weeks.

Anemia is especially apt to occur with pigs farrowed in the winter or early spring in the northern states, because the weather is then usually so cold that the young pigs do not get outdoors to any great extent. Also, they generally have no access to pasture, and the dirt in exercise paddocks may be covered with snow.

Several investigations have been conducted to find practical methods of preventing anemia in suckling pigs.[52] Anemia can readily be prevented by swabbing or spraying the udder of the sow regularly once daily with a saturated solution of ferrous sulfate or other soluble iron salt until the pigs are 4 to 6 weeks old, and also allowing them access to a palatable concentrate mixture, to each 100 lbs. of which has been added 0.1 lb. of the iron salt.

The iron solution may be prepared by dissolving as completely as possible 1 lb. of ferrous sulfate in a quart of hot water. The ordinary grade of ferrous sulfate supplies the very small amount of copper needed to prevent anemia. Another method is to give each pig a dose by mouth of the iron solution once a week.

A less bothersome method that generally prevents anemia is to put fresh sod or soil in the pen at frequent intervals. The pigs will usually root about this and nibble at it, thus getting the necessary traces of iron and copper.

Care should be taken to get the sod or soil from a spot where swine have not grazed for more than a year, to make sure that it does not carry the eggs of round worms or other parasites. Extremely sandy soil that is very low in iron should not be used, unless iron salt is sprinkled on it.

Anemia cannot be prevented by adding an iron salt to the ration fed the sow, because this does not increase the iron content of the milk. Also, adding an iron salt to the ration during pregnancy does not increase the store of iron in the bodies of the pigs at birth enough to prevent anemia.

1404. Trace minerals.—The different trace minerals have been discussed in detail in Chapter VI, and it is there pointed out that trace mineral deficiencies are area problems. In an area where there is a deficiency of cobalt, copper, or any other trace mineral, it is essential that the lack be corrected.

In areas where there are no trace mineral deficiencies, there is no need of supplying trace minerals for swine on good pasture. They undoubtedly secure plenty from the forage and the soil. Even in areas where there are no definite trace mineral deficiencies, there seems to be more often a benefit from a trace mineral supplement for pigs kept in dry lot, than there is in the case of cattle or sheep. This is probably because cattle and sheep eat so much more roughage.

In several experiments there have been increases in rate and efficiency of gains from adding trace minerals to well-balanced rations for pigs fed in dry lot.[53] However, in some trials there has been little or no benefit from supplying trace

minerals.[54] There is more apt to be an appreciable benefit from trace minerals with a ration containing no meat scrap, tankage, or fish meal, than when there is one of these animal products in the ration.

In the studies on trace minerals a mixture of these minerals has usually been fed, and consequently the information is limited as to which trace minerals have actually been beneficial, where improvement has occurred. In some trials where the effect of different trace minerals has been tested, a cobalt supplement or a combination of cobalt and copper has produced a definite benefit.

In some experiments with growing or fattening pigs there has been no benefit whatsoever from adding an iron supplement to ordinary rations, and in other tests the apparent benefit has been very slight.[55] It therefore seems doubtful whether such an addition will generally be profitable.

Information is given in Chapter VI concerning the manganese requirement of swine. (180) Also, the recent studies are there summarized which have shown that parakeratosis, a mange-like disease in pigs, can be prevented and cured by adding a zinc supplement to the ration. (181) As is stated there, a ration that has an excessive amount of calcium increases the occurrence of parakeratosis.

Trace minerals can be provided by using trace mineralized salt instead of ordinary salt. Also, the commercial mineral mixtures for swine now generally contain trace minerals.

1405. Simple vs. complex mineral mixtures.—Whenever swine are fed a ration that is definitely lacking in one or more of the essential mineral nutrients which have been discussed, the deficiency can readily be corrected by giving them access to a mineral mixture that supplies the specific minerals that are lacking. The formulas for various simple mineral mixtures which are well suited for swine are given in Chapter VI. (186)

If calcium is the only mineral that is lacking, there is no need of including in the mineral mixture bone meal or other supplements supplying phosphorus in addition to calcium. Merely such a cheap mixture as ground limestone and salt will be just as satisfactory. On the other hand, when there is a lack of both calcium and phosphorus, then a mineral mixture should obviously be used that supplies both of these nutrients.

The excellent results that have been secured in experiment station tests and on farms with simple mineral mixtures show definitely that there is no need of using more complex mineral mixtures containing such additional ingredients as sulfur, charcoal, coal, sodium carbonate, Glauber's salts, Epsom salts, etc.[56]

1406. Vitamin requirements.—Vitamin A and vitamin D are of great importance in swine feeding, as is shown in the following articles. Fortunately, swine that are on good pasture have their vitamin A requirements amply met through the high carotene content of green forage, and their vitamin D needs taken care of by the anti-rachitic effect of sunlight. In the case of swine not on pasture, the vitamin A and vitamin D requirements can be readily met by using field-cured legume hay as a vitamin supplement.

It is shown later that a supplement furnishing B-complex vitamins is not generally needed for swine fed balanced rations on good pasture. (1410) High-quality legume hay is the best substitute for pasture. Legume hay not only supplies carotene and vitamin D, but also B-complex vitamins, except vitamin B_{12}. (1383) It also furnishes certain unidentified vitamins or factors, which are essential for swine and which may be lacking in some dry-lot rations. (1415)

So far as is known, there is no deficiency of vitamin E in ordinary swine rations. Swine are able to synthesize ample vitamin C in their bodies and do not need a supply in their feed.

1407. Vitamin A and carotene.—Vitamin A is of great importance in pork production, because swine which are not on pasture may suffer seriously from a deficiency of it.[57] The effects of a lack of vitamin A have been discussed in Chapter VII. (192)

Feeds of plant origin owe any vita-

min A value they may have to carotene content, for they do not contain vitamin A. The vitamin A requirements of swine are therefore commonly stated in terms of carotene.

Swine on green pasture are abundantly supplied with carotene. On the other hand, a deficiency is apt to occur when they are fed only grain and other concentrates, unless the grain is yellow corn. As is emphasized later in this chapter, any lack of carotene can readily be prevented by including good-quality alfalfa or other legume hay in the rations of swine in dry lot.

When swine have an abundant supply of carotene, as they do on good pasture, they store considerable amounts of vitamin A in their liver and other tissues. Because of this store, brood sows and well-grown pigs that have been on good pasture in summer may not show any marked deficiency of vitamin A, even if fed for some time in winter a ration lacking in vitamin A value.

The special committee of the National Research Council, in their report mentioned previously, recommends 2.0 milligrams of carotene daily per 100 lbs. live weight for growing and fattening pigs.[2] For growing breeding stock and especially for lactating gilts and sows much more carotene is advised per 100 lbs. live weight. The author has mainly followed these recommendations in the feeding standards given in Appendix Table III.

In its report the committee has also stated the amounts of carotene recommended per pound of air-dry feed, as follows: For breeding stock, 2.5 milligrams per pound of feed; for 25-lb. pigs, 0.25 milligram per pound of feed; and increasing to 0.60 milligram per pound of feed for 250-lb. pigs. The amount of carotene per pound of feed is increased as the pigs grow larger, because they eat less feed per 100 lbs. live weight, and it is believed that the carotene needs are proportional to the live weight.

It is believed that these allowances provide a considerable margin of safety under usual conditions. Much smaller amounts of carotene have been sufficient in experiments with pigs and with brood sows, conducted to determine the minimum requirements.[58]

It has been explained previously that the measurement of vitamin A value in terms of International Units is based upon experiments with rats. (**194**) Swine are much less efficient than rats in utilizing carotene to meet their vitamin A needs. They therefore require about 2.5 times as many International Units of vitamin A value when it is furnished by carotene, as when it is supplied by vitamin A itself.[59]

Brood sows fed rations seriously deficient in vitamin A may fail to come in heat or may not conceive when bred. If they do become pregnant, the pigs are apt to be born dead or very weak.

If pigs are fed a ration that is satisfactory, except for a lack of vitamin A, they may make excellent gains at first and then die later from pneumonia, brought on by lack of the vitamin. Sometimes vitamin A deficiency in swine may be confused with rickets, which is caused by a lack of vitamin D or a deficiency of calcium or phosphorus.

In both cases pigs may become paralyzed so they cannot rise to their feet. In vitamin A deficiency the condition is caused by degeneration of the nervous system, resulting in lack of control of the legs, instead of inability to move them. In walking, the pigs have a peculiar jerky gait, in which the rear legs are thrown out to the side. One of the first symptoms of vitamin A deficiency is often marked restlessness. Later, the pigs may have severe spasms and also show characteristic impairment of vision.

1408. Vitamin D.—Before vitamin D was discovered, swine in this country often suffered severely from rickets when they were confined and had no access to sunlight. As stated in Chapter VII, the most characteristic symptom of rickets in pigs is stiffness of the legs, especially of the hind legs. In severe cases, the hind legs are often paralyzed, because of which condition the disease was sometimes called "posterior paralysis."[60]

When swine are allowed to run outdoors for a considerable part of the day,

where they are exposed to sunlight, the ultra-violet rays in the sunlight usually provide them with plenty of vitamin D, even in winter. (201) In Minnesota experiments, pigs suffering from rickets produced by a lack of vitamin D recovered to a marked extent when exposed to sunlight in winter for only 45 to 90 minutes a day.[61]

When the ration has an ample amount of calcium and phosphorus and also has a proper calcium-phosphorus ratio, swine require much less vitamin D than under other conditions. (152) Because of their rapid bone formation, pigs that are growing very fast require more vitamin D than those that are growing more slowly.

The various breeds of swine seem to differ remarkably in their vitamin D requirements. If they have plenty of calcium and phosphorus, white pigs, at least those of the Yorkshire and the Danish Landrace breeds, may not have any symptoms of vitamin D deficiency under conditions where black or red pigs would be seriously affected. This may be due partly to greater penetration of ultra-violet light into the tissues and a consequent greater storage of vitamin D by white pigs, during any period when they may have been exposed to sunlight.

In Canadian experiments Yorkshire pigs did not show any symptoms of vitamin D lack when confined indoors from weaning time and fed rations practically devoid of vitamin D, but supplying ample calcium and phosphorus.[62] Also, the skeletons of these pigs had a normal mineral content.

In the report of the special committee of the National Research Council, referred to previously, rations containing 90 International Units of vitamin D per pound of feed are advised for swine not exposed to sunlight.[2] The requirement for white breeds is apparently much less.

All common concentrates used for swine feeding are deficient in vitamin D. No appreciable amount is supplied by any of the grains or other seeds, by any of the common concentrates of plant origin, or by tankage, meat scrap, skimmilk, buttermilk, or whey. (204) Some fish meal may supply vitamin D, but it cannot be relied on as a source, unless the vitamin D content is known.

Unless pigs are closely confined and have no access to direct sunlight, an ample amount of vitamin D to prevent rickets even in winter is usually supplied when 5 per cent or more of good-quality field-cured alfalfa or other legume hay is included in the ration. The use of legume hay for this purpose is discussed in detail later in this chapter. (1417)

If pigs are closely confined, it may be advisable to add a vitamin D supplement, even when the ration contains 5 per cent of field-cured legume hay.[63] It should be borne in mind that although dehydrated legume hay is usually richer in carotene than field-cured hay, it generally has very little vitamin D. (204)

1409. Vitamin A or D supplements. —When good legume hay cannot be provided for pigs or brood sows kept in dry lot, a vitamin A or vitamin D supplement should be used.

Cod-liver oil or cod-liver-oil concentrate supplies both vitamin A and vitamin D. Including 0.50 to 1.00 per cent of cod-liver oil or 0.125 to 0.25 per cent of cod-liver-oil concentrate in a ration for pigs furnishes sufficient of these vitamins.[64] Irradiated yeast is an effective vitamin D supplement for swine, but does not furnish vitamin A. Synthetic vitamin A is an effective vitamin A supplement, but of course has no vitamin D value.

Sometimes the inclusion of 5 per cent of field-cured alfalfa hay in a winter ration does not supply quite enough vitamin D for pigs which do not have much exposure to sunlight. Experiments were therefore conducted during 4 winters at the New York (Cornell) Station to find whether there would be a benefit from adding cod-liver oil or cod-liver-oil concentrate to a good ration containing 5 per cent of alfalfa hay.[65] During favorable weather, the pigs had access to small outside paved lots for a few hours daily. However, in this area of New York there is an unusually large proportion of cloudy weather in winter. The pigs therefore had less exposure to ultra-violet light than

there would have been in a sunnier region. Even under these conditions, there was no benefit from an additional A-D supplement, and its use increased the cost of the gains appreciably.

In 7 other similar New York experiments with fall pigs fed in dry lot in winter, the use of cod-liver-oil concentrate as a vitamin supplement was compared with adding 5 per cent of ground field-cured alfalfa hay to the ration.[66] The gains were slightly more rapid and the feed cost per 100 lbs. gain appreciably lower on the ration containing alfalfa hay and no cod-liver-oil concentrate. During the 7 winters, only one pig fed this ration showed any symptoms of rickets. These were mild and the pig made excellent gains throughout the winter. Similar results were secured in 3 Ohio experiments.[67]

1410. B-complex vitamins.—Swine require certain of the B-complex vitamins and are dependent chiefly on the supply in their feed, thus differing from cattle or sheep. This is because there is only a very limited synthesis of these vitamins through bacterial action in the large intestine of swine, while sufficient amounts to meet the needs of ruminants are normally synthesized in the rumen. (208)

Fortunately, when swine are on satisfactory pasture, there are rarely deficiencies of B-complex vitamins. Also, sufficient good legume hay or alfalfa meal usually prevents a lack of these vitamins, except vitamin B_{12}.

The need of young pigs for several of the B-complex vitamins in the diet has been proved by feeding highly purified artificial rations. To prevent the pigs from securing vitamins synthesized in the feces, they were kept on wire screens, or the concrete floor was washed carefully each day.

In such experiments it has been proved that young pigs require thiamin, riboflavin, niacin, pantothenic acid, pyridoxine, and perhaps folic acid. Biotin is also required, but it is synthesized in the body rapidly enough under practical conditions to meet the needs. Inositol and para-amino-benzoic acid do not seem to be needed. References to the reports of the numerous experiments proving the requirements for the B-complex vitamins are given in the report of the special committee of the National Research Council which has been mentioned previously.[2]

In this report the committee recommends that swine rations should have the following amounts of B-complex vitamins. The requirements for all the vitamins except vitamin B_{12} are stated in terms of milligrams per pound of air-dry feed. The requirements of vitamin B_{12} are stated in micrograms (mcg.). A microgram is one-one thousandth of a milligram, or one-one millionth of a gram.

B-vitamin requirements per pound of feed

	25-lb. pigs	50-lb. pigs	100-lbs. and over	Breeding stock
Thiamin, mg. . .	0.5	0.5	0.5	0.5
Riboflavin, mg.	1.2	1.0	1.0	1.2
Niacin, mg. . .	8.0	6.0	5.0	5.0
Pantothenic acid, mg. . . .	5.0	5.0	4.5	4.5
Pyridoxine, mg.	0.6	0.6	. . .	. . .
Choline, mg. . .	400.0	. . .	. . .	. . .
Vitamin B_{12}, mcg.	7.0	5.0	5.0	. . .

The effects of a deficiency of each of these B-complex vitamins are shown in detail in Chapter VII. Any ordinary ration for swine will furnish an abundance of thiamine and also plenty of pyridoxine. There is no lack of choline in most rations that are otherwise satisfactory. The other essential B-complex vitamins are discussed in the following articles.

It is of interest that the amount of thiamine in the lean of pork is considerably increased when pigs are fed a ration rich in thiamine.[68]

1411. Riboflavin.—Such a ration as corn, soybean oil meal, and minerals, with only 5 per cent of alfalfa meal is a trifle low in riboflavin for young pigs in dry lot. The lack can be corrected by increasing the alfalfa meal to 10 per cent; or by substituting meat scrap or fish meal for part of the soybean oil meal; or by

adding a small percentage of a feed rich in riboflavin, such as distillers dried solubles, dried whey, or brewers' dried yeast.

1412. Niacin.—An important fact in swine feeding is that corn and oats contain much less niacin than do barley, the grain sorghums, or wheat. According to average analyses, even when corn and oats are the only grains in a well-balanced ration, the niacin supply will be fully equal to the amounts stated in the previous table of requirements, except for very young pigs.

However, under practical conditions, young pigs in dry lot, fed chiefly on corn or corn and oats, sometimes suffer from diarrhea, or enteritis, because of a lack of niacin.[69] This may be due to variation in niacin content of various lots of grain.

Another reason why niacin deficiency is more apt to occur when corn is the only or the chief grain is that corn is very low in tryptophan. It has been shown in Chapter VII that niacin can be made in the body from tryptophan.[70] (213) Therefore a deficiency of tryptophan accentuates a lack of niacin.

Including alfalfa meal in a ration low in niacin and replacing part of the corn or oats with other grain will correct the deficiency. Also, the niacin supply can be still further increased by adding wheat middlings, meat scrap, tankage, dried distillers solubles, or dried brewers' yeast, all of which are high in niacin.

Such changes in the ration will not prevent or cure the kind of enteritis, or diarrhea, caused by infection and not by nutritive deficiency.[71]

1413. Pantothenic acid.—The most noticeable symptom in pigs of a lack of pantothenic acid is incoordinated, wobbly gait, commonly called "goose-stepping." A deficiency also causes lack of appetite and poor growth.

There may not be sufficient pantothenic acid in balanced rations for young pigs in dry lot, unless care is taken to include a sufficient amount of feeds having a good supply of the vitamin.[72] A deficiency rarely occurs on pasture.

Meat scrap, tankage, and fish meal are all low in pantothenic acid, and the content in the grains is only fair. Soybean oil meal, linseed meal, wheat middlings, and distillers dried solubles have considerably more, and peanut oil meal, dried buttermilk, dried skimmilk, dried whey, brewers' dried yeast, and cane molasses are rich sources.

A ration of grain, balanced only with meat scrap, tankage, or fish meal is apt to be low in pantothenic acid, even if it has as much as 10 per cent of alfalfa meal.

1414. Vitamin B_{12}.—As stated in Chapter VII, many experiments conducted some years ago proved that for pigs in dry lot a ration entirely from plant sources was generally improved by adding a feed of animal origin, such as tankage, meat scrap, fish meal, or dairy by-products. (**220**) The name *animal protein factor* was given to this quality of animal-source feeds.

After vitamin B_{12} was discovered a few years ago, it was found that much of the benefit from the addition of a feed of animal origin to a plant-product ration was due to the vitamin B_{12} it supplied. However, these animal-source feeds also furnish certain unidentified vitamins or factors that may be lacking in dry-lot rations for swine.

Though much less synthesis of vitamin B_{12} occurs through bacterial action in the digestive tract of swine than in the case of ruminants, there is a limited amount in the intestines. This seems to be the reason why in some experiments, when the ration had plenty of cobalt, there has been no appreciable benefit from adding a vitamin B_{12} supplement to a dry-lot ration for swine, which was low in the vitamin.[73] (Vitamin B_{12} contains a small amount of cobalt as an essential constituent.)

Feeds of animal origin, including meat scrap, tankage, fish meal, and dairy by-products are good sources of vitamin B_{12}. Condensed fish solubles and liver meal are especially rich in it, as is also sewage sludge. Feeds of plant origin apparently have little or none, according to the usual methods of analysis.

It is interesting and important that alfalfa hay or meal, even of excellent quality, furnishes only a trace of the

vitamin, as determined by microbiological methods of analysis. Yet swine on alfalfa or other good pasture show no evidence of vitamin B_{12} deficiency, even when fed a ration lacking in the vitamin.[74]

Either sufficient vitamin B_{12} must be synthesized in the intestines of pasture-fed pigs, or else they must secure the mere traces of the vitamin needed from insects and worms they consume.

The minute amount of vitamin B_{12} needed by young pigs in dry-lot is shown in the previous table of B-complex vitamin requirements. The amount of 7.0 micrograms per pound of feed is only 1 part of the vitamin to 64 million parts of feed—indeed a mere trace, though it is essential.

A lack of vitamin B_{12} is much more apt to occur with young pigs than with older ones. In rations that may be deficient in the vitamin it may readily be supplied by a commercial B_{12} feed supplement or by an antibiotic-vitamin B_{12} feed supplement.

1415. Unidentified vitamins or factors.—Swine, at least very young pigs, may require certain unidentified vitamins or factors when they are kept continuously on a screen floor or on concrete which is washed daily. Under such conditions they cannot get an appreciable amount of any such factors which may be synthesized by bacterial action in the feces.

The need of such vitamins or factors is indicated by the fact that it is difficult or impossible to secure maximum growth of baby pigs if they are fed a highly-purified ration containing no natural feed, even when all the known vitamins are supplied. In some experiments baby pigs, removed from the sow a few days after birth and fed such diets, have made better growth when there was added a concentrate of grass juice, or milk, or fish solubles, or certain fermentation residues from antibiotic manufacture.[75] However, in other studies there has been no benefit from such additions to a diet containing all known nutritive essentials.[76]

If young pigs do need unidentified vitamins, they are evidently supplied plentifully by good pasture.

1416. Feeding B-complex supplements.—Whether there will be a benefit from adding a B-complex vitamin supplement to a practical balanced ration for young pigs or older hogs will depend first of all on the nature of the ration. Also, there may be a benefit from such a supplement in the case of unthrifty pigs or pigs that have previously received a poor ration, while there may be no improvement with thrifty pigs, well-fed previously.

As is shown in the preceding discussions of the various B-complex vitamins, there is most apt to be an advantage from adding B-complex vitamins to such a ration as corn, soybean oil meal, minerals, 5 per cent alfalfa meal, and an antibiotic-B_{12} supplement. There is less likely to be a benefit from such an addition to a ration that has an animal protein supplement, or more alfalfa.

In an Indiana trial adding riboflavin, niacin, and pantothenic acid to a good dry-lot ration increased the gains of young pigs 10 per cent.[77] This ration consisted of yellow corn, soybean oil meal, cottonseed meal, fish meal, meat-and-bone scrap, alfalfa meal, a complete mineral supplement, a vitamin A-D supplement, and an antibiotic-vitamin B_{12} supplement. Similar results were secured in a Michigan experiment.[78]

On the other hand, in a Minnesota trial, the addition of the same vitamins to a similar ration produced no benefit, and in a Kansas trial no appreciable improvement.[79]

In Michigan trials young pigs suffering from severe diarrhea caused by inadequate rations were secured from several farms.[80] Most of them recovered when treated with B-complex vitamins and fed a good ration that supplied liberal amounts of vitamins.

Several experiments were conducted some years ago to determine the effect of supplementing rations for pigs with yeast (which is rich in all important B-complex vitamins except B_{12}). In some of the trials the yeast was added to the moistened feed several hours before it was fed, and fermentation allowed to

take place. No matter what method of yeast feeding was used, it was not profitable to add yeast to rations that included such protein supplements as tankage or meat scrap.[81] Generally the rate of gain was not improved and the cost of the gains was increased.

In Ohio experiments, however, there was an appreciable benefit when yeast was grown in a ration of corn, soybean oil meal, minerals, and 5 per cent of alfalfa.[82] Young pigs fed continuously in dry-lot on this ration, without yeast, often did not thrive.

In Wisconsin trials, young pigs fed in dry lot on corn, soybean oil meal, minerals, and only 5 per cent of alfalfa hay did much better when they had access to fresh cattle manure.[83] The benefit was undoubtedly due to the content of B-complex vitamins in the manure. Increasing the percentage of alfalfa hay in the ration to 15 per cent was fully as beneficial as letting the pigs have access to the manure.

In New York tests, adding cow manure to a plant-source ration for pigs in dry lot increased the gains less than did the addition of a trace mineral mixture.[84] The addition was of no benefit with a ration of corn and a trio-type supplemental mixture.

The amounts of the different B-complex vitamins in important feeds are shown in Appendix Tables V, Va, and Vb, so far as information is available. Where the natural feeds in a ration do not supply sufficient B-complex vitamins, a concentrated commercial B-complex supplement will correct the deficiencies.

1417. Legume hay is vitamin insurance.—When well-cured legume hay is available, any lack of vitamins, except vitamin B_{12}, can generally be prevented by including a sufficient amount of such hay in rations for swine not on pasture. This is particularly important for young pigs and for brood sows and boars. Vitamin B_{12} can readily be supplied by including a vitamin B_{12}-antibiotic feed supplement in the ration.

Field-cured legume hay of good quality not only supplies carotene and vitamin D, but it is also an excellent source of the B-complex vitamins, except B_{12}. In addition, it furnishes certain unidentified vitamins or factors that may be needed by swine kept continuously in dry lot. Other benefits from including legume hay are that it is rich in protein and calcium.

Alfalfa hay or alfalfa meal is used more often than other kinds of legume hay for swine. However, other legume hays are satisfactory substitutes for alfalfa, as is shown in the discussions concerning the various kinds of legume hay in Chapter XVI.

Dehydrated alfalfa or other dehydrated legume forage is even richer than field-cured hay in carotene and in B-complex vitamins. However, it generally has very little vitamin D, and therefore does not serve as a vitamin D supplement.

As is shown in the next chapter, brood sows will usually eat enough good-quality alfalfa hay when it is fed uncut in a rack. They are much less apt to eat a sufficient amount of red clover hay, sweet clover hay, soybean hay, or cowpea hay when thus fed.

Growing and fattening pigs often will not consume a sufficient amount of alfalfa or other legume hay for vitamin insurance when it is fed in a rack. The safest plan in feeding pigs not on pasture is therefore to include a definite proportion of high-quality legume hay mixed in the ration.

When young pigs get a good start on pasture before they are put in dry lot and when the ration contains some protein supplement of animal origin, there is generally no need to use more than about 5 per cent of legume hay in the ration. On the other hand, when such a combination is fed as corn supplemented by soybean oil meal and minerals, it is best to increase the proportion of legume hay to 10 or 15 per cent to prevent any vitamin deficiencies.

Experiments have shown that if pigs remain thrifty, they are apt to make slightly more rapid gains and to require less feed per 100 lbs. gain when the ration does not have more than about 5 per cent of legume hay.[85] The difference is especially marked if 15 per cent

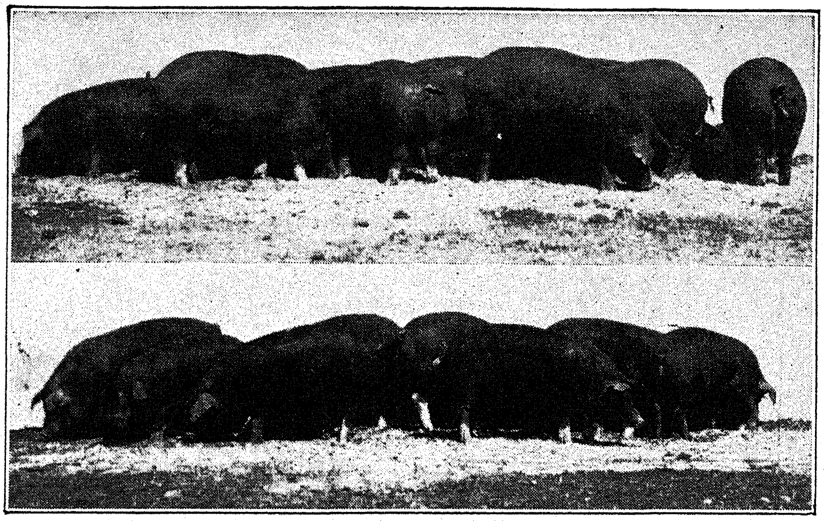
or more of hay is included in the ration.

The results from including a large proportion of high-quality alfalfa meal in the ration for growing and fattening pigs are discussed further in other portions of this chapter. (**1396, 1431**)

Rations for brood sows not on pasture had best contain at least 10 to 15 per cent of well-cured legume hay or else alfalfa meal as vitamin insurance. (**1459**)

provide a supply of vitamins. For these reasons, pigs may not suffer from vitamin deficiencies under farm conditions, although the feeds that they are regularly given would produce disaster if fed under controlled, experimental conditions.

1418. The trio mixtures.—Before the discovery of vitamin D in 1922 and at a time when little was known about the importance of vitamin A for swine,



TRIO MIXTURE EXCELLENT FOR DRY-LOT FEEDING

The trio mixture and similar protein supplements are superior to tankage, meat scrap, or fish meal as the supplement for pigs in dry lot. Pigs in the upper lot, fed yellow corn and the trio mixture, gained faster and were more thrifty than the pigs in the lower lot, which were fed yellow corn and tankage. (From Wisconsin Station.)

If pigs have been raised to a weight of 100 lbs. or more on good pasture, they may have a sufficient store of vitamins in their bodies to enable them to make satisfactory gains up to the usual market weights on a ration somewhat deficient in vitamins. However, even for such pigs it is best to include legume hay in dry-lot rations as a cheap insurance against vitamin deficiencies.

When pigs follow cattle in the barnyard and work over the manure, they undoubtedly secure abundant amounts of B-complex vitamins from the manure, and also more or less carotene and vitamin D. Also, kitchen garbage helps to

investigations were conducted at various experiment stations in an attempt to develop rations which would enable young fall pigs to thrive in dry lot like spring pigs did on good pasture. The author and associates at the Wisconsin Station first found that young pigs in dry lot were greatly benefited by adding good-quality alfalfa hay to such a ration as corn and tankage.[86]

Finally, the author and associates developed a combination of supplements which was decidedly superior to any common single protein supplement for young pigs not on pasture. This was a mixture of 50 lbs. tankage or meat scrap,

25 lbs. ground or chopped alfalfa hay or other legume hay, and 25 lbs. linseed meal.[87]

As is shown later, further experiments at the Wisconsin Station and at other stations have shown that various modifications are satisfactory in this mixture. (**1420**) Such supplemental mixtures are commonly called "trio mixtures."

As is stated later in this chapter, even such an efficient supplement as a trio mixture is generally improved for pigs in dry lot by adding an antibiotic-vitamin B_{12} supplement. (**1422**)

The advantage from using the trio mixture or a similar combination for pigs not on pasture is clearly shown by the results of 31 experiments in each of which one lot of pigs was fed yellow corn and the original trio mixture, while another lot received yellow corn and tankage.[88] The pigs fed the trio mixture gained 1.28 lbs. per head daily until they reached market weights, while those fed corn and tankage gained 1.10 lbs. per day. On the trio mixture an average of 351 lbs. corn and 63 lbs. trio mixture was required per 100 lbs. gain, while on tankage as the only supplement there were required 384 lbs. corn and 44 lbs. tankage. In these experiments each 100 lbs. of the trio mixture saved 70 lbs. tankage and 52 lbs. corn.

The most important advantage of the trio mixture over tankage for pigs not on pasture is not the slight increase in rate of gain or the slight saving in feed required for 100 lbs. gain. The chief merit of the trio mixture and similar combinations is the insurance against some of the pigs becoming unthrifty or even runts, because of a lack of vitamins. It is fortunate, indeed, that this insurance can be gained, not only without added expense, but at an actual saving in cost.

The advantages secured from a trio mixture can mostly be gained by adding merely alfalfa hay to such a ration as grain and tankage. However, experiments have shown that the gains are slightly more rapid and also more economical when corn and such a mixture are fed to young pigs in dry lot, instead of a ration of corn, tankage, and alfalfa hay.[89]

If pigs are well grown on pasture or on grain and such a supplement as a trio mixture until they reach a weight of 100 lbs., they can usually be fed safely on only grain and tankage or meat scrap until they reach the usual market weights. Sometimes the cost of gains may even be a trifle less, after this time, than on yellow corn and the trio mixture.[90] However, it is the safest plan to continue to use the trio mixture or a similar combination until the pigs are marketed, especially in the case of fall pigs fed in dry lot during winter conditions in the northern states. The trio mixtures and similar combinations are satisfactory for feeding to pigs on pasture, but if the pasture is really good, there is no need of including legume hay in the combination of supplements.

1419. Methods of feeding trio-type mixtures.—The trio mixtures and similar supplemental combinations produce excellent results when self-fed, free-choice, as the supplement to shelled corn, also self-fed, or to ear corn that is full-fed. In 3 Wisconsin tests the gains were about as rapid and were slightly more economical when pigs were thus self-fed, free-choice, on shelled corn and the trio mixture, than when a mixture was self-fed which consisted of ground corn and the proper proportion of the trio mixture to balance the ration.[91]

When pigs are fed the grains that are richer in protein than corn (including barley, oats, kafir, and rye) they may eat a larger amount than needed of the trio mixture or similar mixtures, if the mixture is self-fed, free-choice. With such grains, except in the case of wheat, it is generally more economical to mix the proper proportion of supplement with the ground grain and then self-feed the mixture.

1420. Other supplemental mixtures for dry lot.—Many experiments have been conducted by the experiment stations in this country to compare different combinations of protein supplements for pigs fed in dry lot and for those on pasture. Only the briefest summary can be presented here of certain of the most important results of these studies. Some of the conclusions from these experiments

are also given in the detailed information concerning the various protein supplements in Chapters XX to XXIII.

Several supplemental mixtures suitable for feeding, free choice, as the supplement to corn or other grain for pigs in dry lot are given in Appendix Table VII.

To provide insurance against vitamin deficiencies, 25 per cent of alfalfa or other legume hay was included in the original trio mixtures. When such a mixture is self-fed, free-choice, with corn to pigs in dry lot, the legume hay will generally form only about 3 per cent of the total ration. This small proportion is usually sufficient to produce excellent results with the trio mixtures, which contain 50 per cent of tankage, meat scrap, or fish meal. The experiments reviewed previously in this chapter show that a larger proportion of legume hay is often needed to prevent vitamin deficiencies when the ration contains no protein supplement of animal origin.

Supplemental mixtures containing only 10 per cent of legume hay or leaf meal produce very satisfactory results when the pigs are well started on pasture before being confined to dry lot, especially if the mixture contains some fish meal. Thus, in experiments by Vestal at the Indiana Station, the supplemental mixture that ranked first (Purdue Mixture No. 5) was a combination of 20 per cent fish meal, 20 per cent meat-and-bone scrap, 40 per cent soybean oil meal, 10 per cent cottonseed meal, and 10 per cent alfalfa leaf meal.[92] It was found that the fish meal in the mixture could be decreased to 10 per cent, with an increase in the meat-and-bone scrap to 30 per cent, without decreasing the efficiency appreciably.

Soybean oil meal is fully equal to linseed meal when used instead of linseed meal in a trio mixture.[93] Dried distillers solubles is also a good substitute for linseed meal in such mixtures. (**955**) Cottonseed meal can be used in place of linseed meal in such mixtures, but does not usually produce quite as good results. (**918**) Neither wheat standard middlings nor corn germ meal are as good as linseed meal or cottonseed meal in these mixtures.[94] Ground raw soybeans are still less satisfactory.[95]

Fish meal is even superior to tankage or meat scrap in trio mixtures. (**919**)

When meat scrap, tankage, and fish meal are scarce or unusually high in price, the proportion of this kind of feed in the supplemental mixture can be reduced considerably without greatly decreasing the efficiency, if soybean oil meal is used as the substitute. Calcium and phosphorus supplements should then be included in the mixture. For example, a supplemental mixture recommended under conditions in World War II was: 10 per cent of tankage or meat scrap, 40 per cent soybean oil meal, 19 per cent linseed meal, peanut oil meal, or cottonseed meal, 25 per cent alfalfa hay, 3 per cent ground limestone, 1 per cent bone meal, and 2 per cent salt.[96]

Recent experiments have shown that when an all-plant-source ration of corn and soybean oil meal is completely supplemented with minerals, vitamins, and an antibiotic-vitamin B_{12} supplement, growing and fattening pigs in dry lot may make as rapid and efficient gains as when meat scrap or tankage is added.[97] However, for dry-lot feeding an all-plant-source ration requires very careful supplementation to equal a ration that includes a protein supplement of animal origin.

For self-feeding, free-choice, as the supplement to corn or other grain, supplemental mixtures which contain at least 35 per cent of protein are most efficient.[98]

1421. Supplemental mixtures for pasture feeding.—For pigs on good pasture, there is much less difference than for pigs in dry lot between the results from feeding tankage or meat scrap as the only protein supplement and the results from efficient combinations of supplements. This is largely because ample amounts of all the vitamins are supplied by pasture combined with the sunlight pigs get on pasture. Also, good pasture helps to meet the needs for both amount and quality of protein, and it aids in supplying calcium and phosphorus.

However, in numerous experiments with pigs on pasture there has generally been some advantage in using a com-

bination of tankage or meat scrap with soybean oil meal, cottonseed meal, linseed meal, or peanut oil meal, instead of feeding tankage or meat scrap as the only supplement. With such a combination, the gains have usually been slightly more rapid and a little less feed has been required per 100 lbs. gain. Using a mixture of this kind also greatly reduces the necessary amount of tankage or meat scrap, of which there may be a rather scanty supply.

Pigs on pasture will generally make as rapid gains when fish meal is the only supplement to corn or other grain, as when a combination is used of fish meal with cottonseed meal, soybean oil meal, or linseed meal.[99] Whether or not it will be more economical to feed such a combination will depend on the relative prices of fish meal and the other supplements.

A combination of soybean oil meal with tankage, meat scrap, or fish meal is an excellent supplement to corn or other grain for pigs on pasture.[100] In New York experiments in which pigs on pasture were self-fed mixtures of ground corn and various protein supplemental combinations, 3 parts of soybean oil meal to 1 of meat scrap was slightly superior to equal parts of these feeds or equal parts of linseed meal and meat scrap.[101]

Soybean oil meal is liked so well by swine that when a supplemental mixture which consists largely of soybean oil meal is self-fed, free-choice, they may eat more of the supplement than they need. This can be prevented by mixing ground alfalfa hay or mineral mixture in the supplement. (**805**)

Combinations of cottonseed meal with tankage, meat scrap, or fish meal are excellent for pigs on pasture. This is shown by the numerous experiments summarized in Chapter XXII. (**818**) For pigs on pasture, a mixture of one-half linseed meal and one-half tankage or meat scrap is usually a little superior to tankage or meat scrap as the only supplement.[102] However, this combination is slightly excelled by combinations including soybean oil meal.

Kentucky experiments show that a combination of soybean oil meal and dried corn distillers solubles is an excellent protein supplement for pigs on pasture.[103]

The trio mixture and similar combinations that include legume hay are satisfactory for feeding to pigs on pasture, but if the pasture is really good, there is no need for having legume hay in the supplemental mixture as vitamin insurance.

In Indiana experiments, Purdue Supplement C ranked first in rate of gain for self-feeding, free-choice, with corn to pigs on pasture.[92] This mixture is the same as Purdue Supplement 5 for dry lot feeding which has been mentioned previously, except that it contains 10 per cent of linseed meal in place of 10 per cent of alfalfa leaf meal. The average gain was slightly more rapid on this mixture than on a simple mixture of one-half soybean oil meal and one-half meat-and-bone scrap. However, there was no appreciable difference in the amount of feed required per 100 lbs. gain, or in the cost of the gains. In 2 tests Supplement 5, which included 10 per cent of alfalfa leaf meal, was as satisfactory as Supplement C for pasture feeding.

1422. Antibiotic supplements for pigs.—During the past few years literally hundreds of experiments have been conducted to determine the effects of adding an antibiotic feed supplement or a pure antibiotic to swine rations.[104]

As has been pointed out in the general discussion of antibiotic feed supplements in Chapter XXIII, most of the antibiotic supplements on the market supply not only an antibiotic or a mixture of antibiotics, but also vitamin B_{12}. (**966**) Such a supplement is called an antibiotic-vitamin B_{12} feed supplement. The effect of this kind of supplement may obviously be due both to the antibiotic and also to vitamin B_{12}.

Most of the antibiotic-feeding experiments have been with growing and fattening pigs. A few have been with pigs before weaning or pigs taken from the sows a few days after birth and fed a milk substitute. Some have been with

brood sows through pregnancy and lactation.

In the greatest number of trials, aureomycin (chlortetracycline) has been tested, but several experiments have been conducted with terramycin (oxytetracycline), penicillin, bacitracin, and streptomycin. Very little information is available concerning the effects of other antibiotics in swine feeding.

An effective level of antibiotic is 5 milligrams per pound of total ration, or 10 grams per ton.[2] For a protein supplemental mixture to be fed with grain, about 25 milligrams per pound of the supplement, or 50 grams per ton is recommended.

In a recent survey of the results of the experiments on antibiotic supplements for swine, Braude, Wallace, and Cunha found that under normal conditions of health, adding an aureomycin or terramycin supplement to rations for growing and fattening pigs increased the gain about 15 per cent, and reduced the amount of feed required per 100 lbs. gain by 2 to 5 per cent.[104] Terramycin has apparently not been quite so effective as aureomycin in the majority of such comparisons. In this survey they report that penicillin, streptomycin, and bacitracin have been somewhat less beneficial than aureomycin or terramycin, increasing the average gain about 10 per cent.

In 227 trials in which aureomycin, terramycin, penicillin, or streptomycin were added to rations, the rate of gain was not increased in 20 tests, and the feed efficiency was not improved in 45 comparisons.

In a few experiments a mixture of antibiotic supplements has been compared with single antibiotic supplements.[105] The results have differed, and at present there are insufficient data to conclude that such a mixture is more effective than aureomycin or terramycin as the single antibiotic supplement.[2]

In the case of unthrifty or runt pigs and pigs fed poor rations, an antibiotic-vitamin B_{12} supplement usually is much more beneficial than with thrifty pigs fed good rations. However, such a supplement is no substitute for efficient rations and careful sanitation.

The improvement from an antibiotic-vitamin B_{12} supplement is generally greater with an all-plant-source ration than with a ration containing a protein supplement of animal origin. In most of the experiments with pigs on good pasture, an antibiotic supplement has increased the gain, but often the increase has been less than in dry-lot trials.[106] In some of the pasture tests the antibiotic supplement has not reduced the amount of feed required per 100 lbs. gain enough to cover the cost of the antibiotic.

The greatest increase in rate of gain from an antibiotic supplement occurs during early growth. However, there is usually some benefit after pigs reach a weight of 100 to 125 lbs. Experiments have proved that the rate of gain from weaning to market weights is generally more rapid and the feed efficiency higher, when the antibiotic supplement is fed continuously until the pigs are ready for market.[107]

Opinions differ as to whether or not the requirement for protein is reduced by an antibiotic supplement.[108] In some tests there has seemed to be a protein-sparing effect, but in fully as many trials there was no such result.

An antibiotic supplement may slightly increase the proportion of fat in the carcass. However, if antibiotic-supplemented pigs are marketed at the same weight as those not fed an antibiotic supplement, there will be no significant difference in the depth of back fat, or in the proportions of fat and lean in the carcasses.[109] Nevertheless, for the production of high-quality bacon carcasses, it may be undesirable to continue the antibiotic supplement during the finishing period.[110]

The implanting of an antibiotic pellet under the skin of an ear of baby pigs has been suggested, as a means of administering the antibiotic before the pigs eat much solid food. However, in most of the tests, such implantation of an antibiotic has not been beneficial.[111]

In Minnesota trials, adding an aureomycin or terramycin supplement to the

creep feed for suckling pigs increased the gains.[112] Penicillin was less effective, and bacitracin did not improve growth. In trials by the United States Department of Agriculture, adding an aureomycin-vitamin B_{12} supplement to the creep feed increased the gains of suckling pigs.[113]

If pigs are removed from the sows at only a few days of age and fed a milk substitute, an antibiotic-vitamin B_{12} supplement should be included in the mixture. This will reduce scouring and mortality, as well as increase growth.[114]

1423. Antibiotic supplements for sows.—Several experiments have been conducted recently to find whether or not there was a benefit from adding an antibiotic supplement to a good ration for brood sows during gestation and lactation.[115] In most of the trials such a supplement has not been beneficial.

If an antibiotic supplement is included in a ration for sows suckling pigs, the pigs may eat some of the sow feed, and the weaning weight of the pigs be thus increased. No appreciable amount of antibiotic from the sow's feed is transferred into her milk.

1424. Arsonic supplements; surfactants.—Several experiments have been carried on recently to find whether there was an improvement from adding a small amount of arsonic acid or some other organic arsenic compound to rations for pigs.[116] (**967**) In the majority of the trials these supplements have been ineffective, or less beneficial than an antibiotic.

In cases where pigs are affected with bloody dysentery, an arsenical supplement aids in controlling the disease.

In most of the experiments in which a surfactant, or surface-active-agent, has been added to a ration for pigs, either the surfactant has not been beneficial, or else it has caused less improvement than an antibiotic supplement.[117] (**967**)

1425. Hormones.—Differing from the results with fattening cattle, adding stilbestrol (diethylstilbestrol) to rations for growing and fattening pigs has not increased the gains or feed efficiency.[118] (**1183**) Also, intra-muscular or subcutaneous injection of other sex hormones has little or no effect on gains.[119]

Experiments have been conducted to find whether the growth of pigs could be increased by adding thyroprotein to the ration. (**54**) In other trials the effect has been studied of adding thiouracil or thiourea to the rations of well-grown pigs during the later stages of fattening. The latter drugs suppress the secretion of thyroxine by the thyroid gland, and hence slow up body metabolism. They are called goitrogens, because they cause enlargement of the thyroid.

With reference to the use of thyroprotein in swine feeding, the committee on hormones of the National Research Council states, "The most successful use of thyroprotein has been obtained with young growing pigs, but even in young swine the results have been variable, and the effects of several factors that may influence results are not well defined." [120]

Concerning the addition of thiouracil or thiourea to rations for pigs, the committee states, "The use of goitrogens in swine husbandry must be considered to be still in the experimental stage. Whether or not the goitrogens presently available, used in such ways as have been tried to date, are suitable for use in pork production is a question that has not received a final answer.

"However, some goitrogens have produced significant increases in efficiency of utilization of feed without markedly decreasing rates of gain when they have been employed during the last 4 weeks of the fattening period. Administration of goitrogens for more than 6 weeks has depressed growth rates significantly.

"The possible danger to consumers of pork and pork products from retention of thiouracil is recognized, but this danger is negligible if goitrogen feeding is avoided during the last 3 days prior to slaughter."

1426. Water.—Swine should always be supplied with plenty of water. The amount of water consumed by pigs ranges from about 12 lbs. daily per 100 lbs. of animal at weaning time down to 4

lbs. or less per 100 lbs. live weight during the fattening period.[121] More water is of course needed in hot weather than in winter.

The amount of water consumed per head daily by brood sows was 7.5 lbs. in an Iowa test with pregnant yearling sows and 43 lbs. in an English test with brood sows suckling litters.[122]

Watering swine by means of an automatic waterer not only saves labor, but also insures a plentiful supply at all times. However, pigs given plenty of water in a trough two or three times a day apparently make as rapid and economical gains as those watered by means of an automatic waterer.[123]

In very cold winter weather, swine watered in a trough may not drink enough for the best results unless the water is warmed enough to keep it from freezing soon after it is put in the trough. In winter there is no need of warming water in an automatic waterer more than enough to keep it from freezing.[124]

Growing and fattening pigs self-fed on pasture graze the various parts of the pasture more uniformly if the water supply is not close to the self-feeder. However, South Dakota results indicate that in hot weather the water should not be more than about 300 feet from the self-feeder.[125]

III. General Problems in Pork Production

1427. Prices of hogs during the year.—In deciding upon the best plan of pork production to follow, one should consider the average prices of hogs on his own market for various months in the year. By having pigs ready for market at the time when the price is usually highest, the profit can commonly be increased decidedly.

The number of pigs farrowed in the spring in this country is much greater than of those born in the fall, and the bulk of these spring-farrowed pigs reach the market from late October to February. During this period the supply of hogs on the central markets is therefore the heaviest, and as a result the price is considerably lower than during the rest of the year.

If not artificially controlled, the average prices of hogs in the markets of this country are highest in August and September, when the receipts of hogs are lowest.[126] In October the average price begins to drop sharply, as the spring-farrowed pigs start to come to market in large numbers. The average price reaches the lowest levels from November through January, when the marketings are heaviest. The price then begins to recover and usually reaches a lower secondary peak in March. In April and May the price generally recedes somewhat, when the bulk of the fall pig crop comes to market. Then in June the rise begins to the August–September peak.

The farmer who has facilities for taking proper care of early spring litters can usually secure the highest price by having them ready for market before October. This means, however, that the pigs must be liberally fed on efficient rations and must have the best of care, or they will not reach a market weight of 200 lbs. or more by that time. Instead, they will get to market in November or December, when prices are low.

It is shown in the next chapter that farmers who raise early spring litters for marketing before the slump in price occurs in the fall, usually find it profitable to breed as many sows as possible for fall litters, as well. These are ready for market in spring, when prices have recovered.

1428. Limited-feeding vs. full-feeding of pigs.—One of the most important questions that every hog raiser must decide is how much grain he will feed his growing, fattening pigs. He knows that the larger the amount of grain or other concentrates he feeds, the faster they will gain, no matter whether in dry lot or on pasture, but he wonders whether or not he will make more profit if he restricts the amount of concentrates.

It has been shown previously that animals fed liberal rations tend to digest and utilize their feed with slightly less efficiency than those that receive limited

rations. (101) However, if a growing and fattening animal, such as a pig, is fed a limited ration, a longer time will be required before it reaches the desired market weight and the proper degree of fatness. This will increase the amount of feed required for mere body maintenance during the growing and fattening period, and therefore reduce the proportion of feed available for producing gain in weight.

These two factors therefore tend to have an opposite effect on the relative amounts of feed required per 100 lbs. gain by pigs that are full-fed and by those that are fed limited rations. The net effect of limited feeding can be determined only by experiments in which pigs are full-fed in direct comparison with others that receive limited amounts of the same feeds. It is important that such tests be continued until the limited-fed pigs have reached market weights, which has not been done in some of the experiments on this problem.

1429. Effect of feeding level on the carcass.—The experiments of Hammond and McMeekan, summarized in Chapter IX, showed that the proportions of lean and fat in hog carcasses could be changed appreciably by methods of feeding. (283) By feeding a liberal ration until pigs were well grown, and then limiting the feed intake during the finishing period, a larger proportion of lean and less fat was produced than when pigs were full-fed continuously.

The restriction in nutrient intake can be made either by feeding a reduced amount of an ordinary ration, or else by including in a full-fed ration a suitable amount of a very bulky feed, such as ground alfalfa or other hay. Ground corn cobs can be used similarly, but they merely dilute the ration and do not furnish much digestible nutrients to pigs.

The increase in the proportion of lean in the carcass is desirable, from the standpoint of our present market demand for leaner pork. However, this advantage may be offset by the fact that pigs which have had their net energy supply restricted will commonly yield an appreciably lower percentage of dressed carcass.

Where high-quality bacon carcasses command a considerable premium, as in Canada, it is generally most profitable to produce pigs that meet these requirements. On the other hand, on most of the United States markets such pigs do not bring a sufficient premium at present to warrant much additional expense in producing them.

1430. Limited feeding in dry lot.—Experiments have been conducted recently by the Minnesota and Missouri Stations to compare full-feeding continuously with the method of full-feeding until the pigs reached a weight of 125 lbs., and then feeding them only 75 to 85 per cent of a full ration.[127] In each experiment another group was fed the limited ration throughout the trials.

In 3 experiments the pigs fed liberally until they reached market weights gained an average of 1.46 lbs. a day and required 395 lbs. of feed per 100 lbs. gain. Those fed liberally at first and then fed the restricted ration during the finishing period gained 1.34 lbs. a day, and they needed 9 days longer to reach the same market weight. However, they required no more feed per 100 lbs. gain.

The pigs fed the limited rations continuously gained only 1.13 lbs. a day and it took 41 days longer for them to reach market weight than for the full-fed pigs. In spite of this, they needed slightly less feed per 100 lbs. gain than the other lots.

Such moderate restriction of feed during the finishing period produces desirable leaner carcasses, but the dressing percentage is usually about 2 per cent less than for full-fed pigs. In some cases the lower dressing percentage fully offsets the higher value of the leaner carcasses.

If the amount of feed for pigs in dry lot is still further reduced, the gains will be poor, and much more feed will be needed per 100 lbs. gain. This is because the pigs then need most of their feed for maintaining their bodies.

For example, in 2 New York tests pigs fed only a half ration from an aver-

age weight of 62 lbs. until they reached market weights gained only 0.65 lb. a day and required 428 lbs. of feed per 100 lbs. gain.[128] Others full-fed the same well-balanced feed mixture gained 1.39 lbs. and required only 391 lbs. of feed per 100 lbs. gain. Such scanty feeding therefore not only wasted feed but also doubled the amount of labor.

In addition, if the feed is restricted too much, the pigs will not be sufficiently fat at the usual market weights to yield high-quality carcasses.

It is sometimes advocated that to save grain, pigs in dry lot should be fed a decidedly limited ration until they reach a weight of 100 to 150 lbs. and then be full-fed until they are ready for market. However, this method is usually uneconomical, in comparison with continuous full-feeding or with full-feeding at first and finishing the pigs on a moderately limited amount of feed.[129]

If one is raising fall pigs to follow fattening cattle, it may be desirable to limit their feed slightly. Also, some farmers feed fall pigs a limited amount of concentrates during the winter, and then finish them on pasture in the spring. Ohio tests indicate that this is doubtful economy, unless grain is very high in price in comparison with the cost of pasture.[130] Too often such fall pigs are fed so little during the winter that their gains are exceedingly expensive and they may even become unthrifty because of stingy feeding.

1431. Restricting nutrients by adding roughage.—It has been mentioned that when it is desired to produce leaner carcasses, the nutrient intake during the finishing period may be reduced by including very bulky feed in the mixture and then self-feeding it. In a Wisconsin trial economical gains were made and good carcasses were produced when 28 per cent of ground low-grade alfalfa hay or 16 per cent of ground corn cobs was included in a self-fed mixture.[131] A larger proportion of the bulky feeds increased the cost of the gains, and the carcasses were not firm and graded lower.

In an Oklahoma experiment the nutrient intake was reduced after the pigs reached 140 lbs. in weight by adding 20 per cent of ground prairie hay to a self-fed mixture.[132] The pigs finished on the low-energy ration gained 0.23 lb. a day less than others self-fed the usual ration and required 76 lbs. more feed per 100 lbs. gain. They did not like the prairie hay mixture and wasted considerable feed around the self-feeders.

When one wishes to limit the nutrient intake on a self-fed mixture, it would seem preferable not to add a low-grade feed, but instead to include enough good-quality ground legume hay to have the desired effect.

1432. Limited-feeding on pasture.—Full-feeding pigs on pasture is generally much more profitable than limited-feeding, if the pigs are farrowed early enough in the spring so they can be fattened for marketing early in the fall, before the usual slump in price occurs.

With late spring pigs, the profit may be greater if they are fed only enough concentrates to keep them growing well during the summer and if they are then fattened on the new corn crop in the fall and early winter for marketing in January or February, after the price recovers somewhat. Pigs to be used in the fall for hogging-down corn or for following fattening cattle should also be fed a limited amount of grain in the summer, so they will be in thrifty feeder condition.[133]

Many trials have been conducted to compare full-feeding of pigs on good pasture throughout the season with feeding only a limited amount of grain during the pasture season, and then finishing them in the fall by full-feeding. In 32 such experiments pigs averaging 58 lbs. in weight at the start were fed to market weights on good pasture.[134] Those which were full-fed (usually self-fed) all the time gained an average of 1.45 lbs. a day and consumed 369 lbs. of concentrates per 100 lbs. gain. Pigs fed a limited amount of concentrates until fall and then finished by full-feeding gained 1.14 lbs. a day and needed 31 days longer to reach approximately the same market weight. These pigs, however, required a trifle less concentrates

(7 lbs.) per 100 lbs. gain, but they undoubtedly ate more pasturage. These data show clearly that under conditions in the corn belt it will commonly be most profitable to full-feed early spring pigs on pasture, so that they can be sent to market before the price declines severely.

This is also proved by a study of the net returns from early-spring litters on 43 Indiana farms where the pigs were fed limited amounts of grain during the first 3 months after weaning and on 24 farms where the full-feeding method was used.[135] The full-fed pigs were ready for market on September 27, on the average, and sold for 97 cents more per hundredweight than the limited-fed pigs, which were not ready for market until December 10. For each 100 lbs. gain the full-fed pigs required only 6.1 bushels corn and 8.2 lbs. tankage, while the limited-fed pigs needed 8.7 bushels corn and 6.6 lbs. tankage. The death loss after weaning was also in favor of the full-fed pigs, being only 2.5 per cent, in comparison with 7.5 per cent for the other pigs.

The total cost of 100 lbs. gain, including not only feed cost but also all other expenses, was 15 per cent less for the full-fed pigs, and the profit was therefore much greater.

For late spring pigs on good pasture or in the southern states for fall pigs, it may be desirable to limit the amount of concentrates somewhat, as the longer time needed to reach market weight may then be an advantage. Late spring pigs or fall pigs fed on good pasture may be ready for market after the bulk of the spring and fall pigs have been sold and thus bring a good price. Limited feeding, especially during the finishing period, will also produce leaner carcasses.

In Tennessee experiments pigs fed 80 or 60 per cent of full feed on good pasture made considerably cheaper gains than those which were full-fed.[136] Those fed the 80 per cent ration yielded high-quality carcasses, but the dressing percentage was 1.7 per cent less than for the full-fed pigs. The carcasses of the pigs fed the more limited ration lacked somewhat in finish.

In the alfalfa districts of the West it is often most profitable to limit the allowance of grain for pigs during the summer, for pasture is very cheap in comparison with grain.[137] This method is commonly used in the sections that specialize in the production of feeder pigs for shipment to the corn belt. Even when the pasture is excellent, it is necessary to feed 1.0 to 1.5 lbs. of grain per head daily to growing pigs, in order to keep them growing thriftily and making the desired gain in weight. Whether or not to feed a protein supplement to pigs receiving a limited amount of grain on first-class pasture has been discussed earlier in this chapter. (**1393**)

1433. Self-feeding.—Numerous experiments have proved that the feeding of fattening pigs by means of a self-feeder is efficient and economical. Pigs that are self-fed suitable rations not only make slightly more rapid gains than those that are hand-fed two or three times a day all they will eat, but also they usually require slightly less feed per 100 lbs. gain. In addition, considerable labor is saved.

Self-feeding is not only an excellent method of full-feeding fattening pigs or fattening sows, but it is also a good way to feed brood sows and their litters. It is not a satisfactory method of feeding pregnant sows, unless considerable bulky feed is included in the mixture that is self-fed. Even then, care is needed to keep the feeds so proportioned that the sows do not gain too much or too little. Therefore, hand-feeding pregnant sows is a much more common practice than self-feeding. (**1466**)

In self-feeding swine, grain and protein-rich supplements may be fed, free-choice, in separate compartments of the self-feeder, or the pigs may be self-fed a properly balanced mixture of grain and protein-rich supplements. The merits of these two methods have been discussed previously. (**1391**)

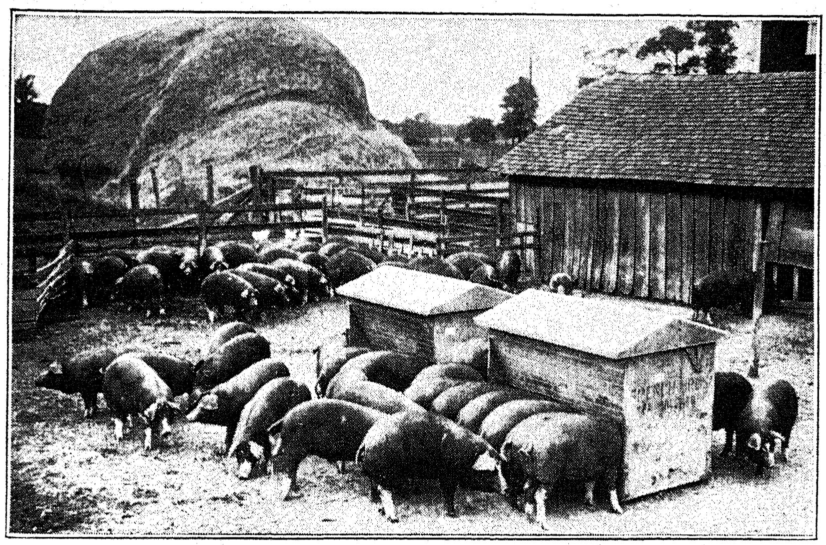
Although self-feeders are labor savers, they need daily inspection to make sure that none has become clogged or is out of adjustment so that feed is being wasted. If grain and a protein

supplement are being self-fed, free-choice, supplies of both should be available to the hogs at all times.

1434. Self-feeding vs. hand-feeding.—The excellent results secured when a self-feeder is used for fattening pigs are shown by 24 tests, in each of which one lot of pigs, not on pasture, was self-fed, free-choice, on such a ration as corn and protein supplement.[138] In each test another lot was hand-fed a well-balanced ration of the same feeds.

The self-fed pigs ate 0.6 lb. more corn per head daily than those which were hand-fed twice daily all they would clean up. This is the usual result and is due to the fact that self-fed pigs help themselves many times a day and even during the night, thus being "full-fed" at all times. Naturally, they gained a trifle more rapidly than those which were hand-fed, the average daily gain being 1.59 lbs. for the self-fed pigs and 1.42 lbs. for those which were hand-fed. Most important of all, is the fact that 11 lbs. less concentrates were required for 100 lbs. gain by the self-fed pigs. This is not a large saving in itself, but to it are added the advantages of the more rapid gains and the saving of labor by self-feeding.

That self-feeding is also an economical method of feeding pigs on pasture has been well proved. For example, in 9 trials pigs self-fed corn and tankage, free-choice on good pasture, gained 1.32 lbs., compared with 1.20 lbs. for others hand-fed the same feeds.[139] On the average the self-fed pigs ate 4 lbs. more tankage per 100 lbs. gain, but took 1 lb. less corn. This slight difference of 3 lbs. total feed per 100 lbs. gain in favor of the hand-fed pigs would, however, ordinarily be more than offset by the saving in labor through self-feeding and by the greater rapidity of the gains.



SELF-FEEDING IS EFFICIENT AND ECONOMICAL

Pigs self-fed in dry lot gain more rapidly than those which are hand-fed and require a trifle less feed per 100 lbs. gain.

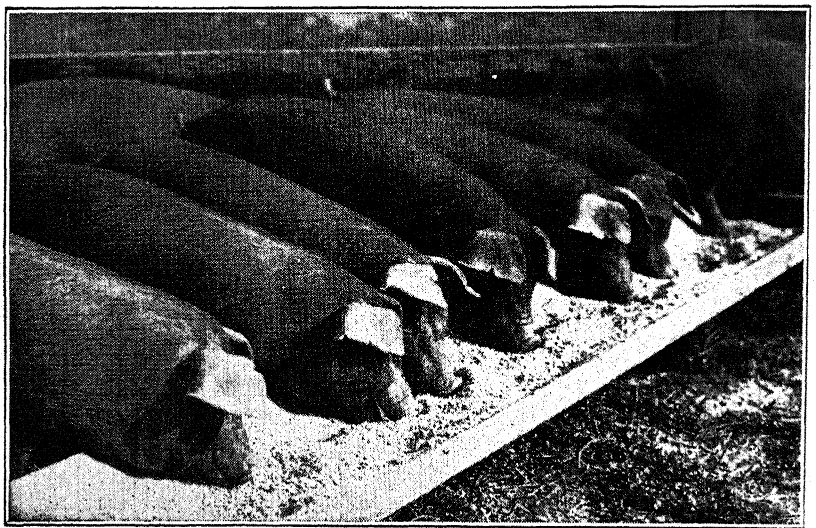
1435. Grinding grain for swine.—Whether or not it will pay to grind any particular kind of grain for swine depends on the completeness with which they chew it when unground. Definite information on this question is given for each kind of grain in Chapters XX and XXI.

In general, it does not pay to grind corn for pigs up to the usual market weights, or for brood sows. Instead, ear

corn or shelled corn is commonly fed. There is generally enough saving through grinding barley, oats, or millet to make such preparation decidedly profitable. If wheat and the grain sorghums are fed in self-feeders, pigs usually chew the grain with sufficient thoroughness so that grinding does not pay. On the other hand, when these grains are hand-fed, there is considerably greater saving through grinding.

When a finely ground mixture is fed outdoors in a windy location, slop-feeding may be advisable, merely to prevent feed being blown from the trough and wasted. Also, in very cold weather it may be advisable to feed a warm slop, so the hogs will get enough water.

With the exception of a few feeds, cooking feed for swine decreases its value, instead of increasing it.[142] Potatoes, soybeans, field beans, and velvet beans are greatly improved by cooking.



HAND-FEEDING REQUIRES MORE LABOR

Unless one wishes to feed pigs a limited ration, self-feeding is more efficient than hand-feeding.

1436. Soaking grain; feeding slop; cooking feed.—If shelled or ear corn becomes very hard and dry on storage, it may pay to soak it before feeding to swine, though the increase in value is not usually very marked. When whole barley or oats cannot conveniently be ground, it may be economical to soak the grain, though soaking it is a rather poor substitute for grinding. It does not generally pay to soak ground grain or a mixture of concentrates for swine.[140]

Years ago it was a common practice to feed grain mixtures to swine in the form of slop or swill. Experiments have shown, however, that slop-feeding is not generally superior to dry-feeding.[141]

1437. Pelleted feed.—A general discussion of pelleting feed has been given in Chapter IV. (91) As there stated, the cost of pelleted feeds compared with ordinary rations will largely determine whether pelleted feeds will be economical. For feeding growing and fattening pigs the entire ration, including ground grain, may be pelleted, or a pelleted protein supplemental mixture may be self-fed, usually free-choice, with corn or other grain.

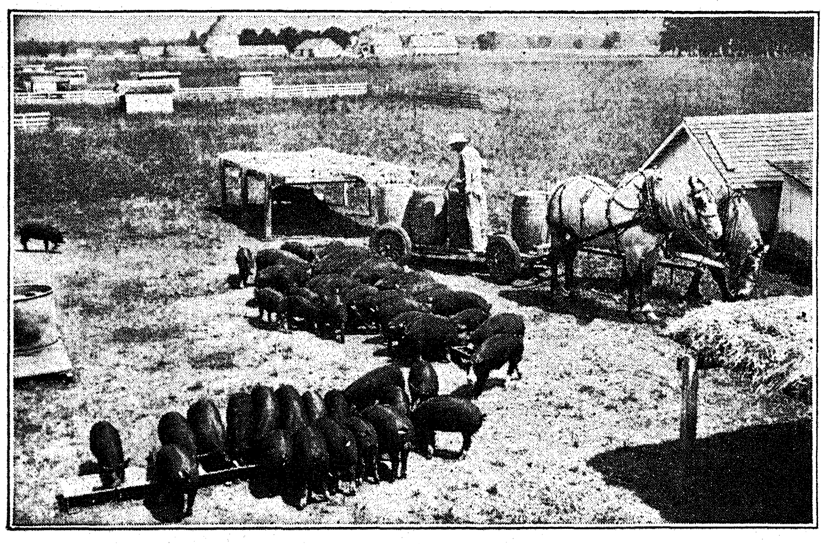
Several experiments have been conducted recently to compare pelleted feed with usual rations for pigs.[143] In these trials a self-fed pelleted ration of such a

mixture as ground barley and supplements has generally produced appreciably more rapid gains than self-feeding the same mixture in meal form. Also, less feed has usually been required per 100 lbs. gain on the pelleted ration.

The saving in feed needed per 100 lbs. gain by pelleting such a ration has differed widely, ranging from 8 per cent to more than 40 per cent in a case where there was much wastage of the meal ration around the self feeders. Usually the

When ear corn is fed in summer on pasture lots that are free from infestation with parasites, there may be no appreciable advantage in using feeding platforms.[145]

1439. Temperature; shade; wallows.—Because swine have little ability to get rid of excess heat, they suffer greatly in very hot weather unless they have access to a wallow where they can wet their bodies, and unless good shade is provided. (233–234)



SLOP-FEEDING HAS BEEN MOSTLY DISCONTINUED

Slop-feeding is not generally superior to dry-feeding, and it requires more labor.

saving by pelleting a ration of this kind will not be more than about 20 per cent. There is apparently much less advantage in pelleting a mixture of ground corn and supplements.

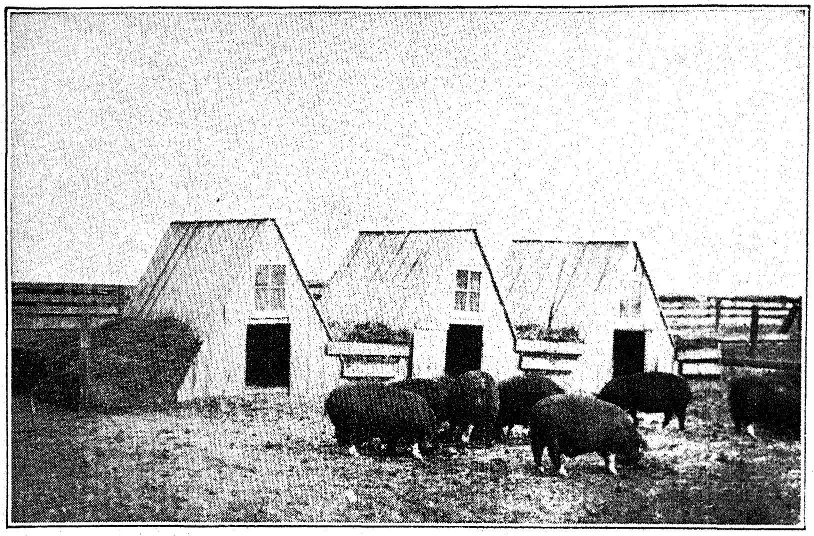
1438. Feeding platforms.—It is advisable to place self-feeders on platforms in the pasture or outside lot, so that the pigs can salvage feed that may be nosed out of the self-feeder. It also pays well to have feeding platforms in hog lots where ear corn is fed during the rainy season. Thus, in a Kentucky test during the fall, the feed cost of 100 lbs. gain was 14 per cent less when ear corn was fed on a platform than when it was fed on the muddy ground.[144]

In California experiments in which swine were kept in rooms where the temperature and the humidity were both controlled, a continued air temperature of 100° F. even caused death, if the skin was not wet.[146] The cooling effect of evaporation from the wet body surface was very important at high air temperatures.

The importance of shade in hot weather is shown by Mississippi trials.[147] Exposure to sunlight for only 15 minutes at air temperatures of 82 to 90° F. caused distress in pigs, raising the body temperature and greatly increasing the respiration rate. Providing good shade for growing and fattening pigs increased the

gain and the feed efficiency. These experiments show that where the summer weather is very hot, it is extremely important to provide a sanitary concrete or portable wallow for swine, and also plenty of shade.[148]

In the California studies, pigs weighing 50 to 125 lbs. made the most rapid and efficient gains at an air temperature of about 73° F., while a temperature of about 61° F. was optimum for heavier hogs.



COLONY HOUSES BANKED WITH STRAW FOR WINTER

Colony houses thus protected provide comfortable winter quarters for all but small pigs, even in the northern states.

Where the summers are very hot, pigs make more rapid and more economical gains in winter than in summer.[149]

1440. Shelter.—Even where the winters are cold, inexpensive shelter is all that is necessary for swine. The essentials for healthful winter shelter are freedom from dampness, good ventilation without drafts, sunlight, reasonable warmth, and a moderate amount of dry bedding. The quarters should be on well-drained ground and be so arranged that they can be thoroughly cleaned and disinfected.

Swine may be housed in a central hog house with a number of pens or in small portable houses, or colony houses. Many use a combination of the two systems, for in the northern states the central house is well suited for winter shelter and early spring farrowing, while the portable houses are particularly useful for housing pigs on pasture.

Portable houses may also be used for winter shelter, even where the weather is cold. They will be fairly warm if corn stalks, horse manure, or other litter is banked against the sides of the houses. A strong sack may be hung in the doorway to keep out the cold and yet allow the hogs to go back and forth at will. For very young pigs a lantern may be hung in the portable house to keep the temperature comfortable.

Even in the northern states, brood sows wintered in cheap portable houses do not require much more feed than do those in a central house, especially if the houses are well protected. In trials during 4 winters at the Wisconsin Station, pregnant gilts were wintered in shed-roof colony houses made of a single thickness of boards.[150] The opening through which the sows entered was left open

at all times so they could come and go at will, and no litter was banked up against the houses to make them warmer. At farrowing time the sows were removed to farrowing pens in the central barn.

The feed cost of wintering these sows was 16 per cent higher than for sows kept in a central hog barn and allowed to run at will in an exercise paddock during the day. However, this greater feed cost was offset by the fact that a larger proportion of the pigs from the sows housed in the portable houses were vigorous. This was probably because the sows took more exercise; they were out in the sunlight more; and they were able to get a small amount of green grass from the paddocks in which the portable houses were located. All these factors are important in enabling sows to produce thrifty litters.

For very young pigs, there is more advantage from warmer shelter. In the northern states a well-ventilated central hog house is therefore best for sows that farrow in cold weather. However, even in the northern part of the corn belt, many farmers raise early spring pigs very successfully in well-protected colony houses.

Fall pigs that get a good start before cold weather comes on will do well in portable houses during northern winters. For example, in 3 Michigan trials fall pigs housed in portable houses during winter made as rapid gains as those in a central house, and they required no more feed per 100 lbs. gain.[151]

Where the winters are more severe, a considerable saving in feed may be made by providing warmer shelter. Thus, at the Ottawa, Ontario, Station pigs weighing 70 lbs. at the start that were housed in portable houses during the winter required 44 per cent more feed than others in a well-built central house.[152] Brood sows in the portable houses required only 25 per cent more feed than those in the warmer quarters, showing that large animals can withstand severe cold better than small ones. The health of the animals was good under both conditions.

EXERCISE IS IMPORTANT FOR BROOD SOWS IN WINTER

Brood sows housed in these unprotected colony houses at the Wisconsin Station required 16 per cent more feed than those kept in a central hog house, but the percentage of vigorous pigs they farrowed was higher, because they took more exercise.

In a Kansas test during a winter in which the temperatures at 8 a. m. ranged from 31° F. to −12° F., large hogs in warm quarters required 25 per cent less feed than those kept without shelter in a yard protected only by a high board fence on the north.[153]

1441. Exercise.—Sufficient exercise is highly important for breeding swine and also for young pigs.[154] Even for fattening pigs, limited exercise is preferable to very close confinement. In addition to the benefits from the exercise itself, when

swine are out-of-doors in outside paddocks a considerable part of the day they are protected against a deficiency of vitamin D, through the effect of direct sunlight. Also, swine that have access to outside paddocks may get some green feed, even during the winter. Though the amount of green forage they eat may be small, it is often of much value in keeping them thrifty.

So that brood sows will exercise in winter, it is advisable to feed them at the end of the paddock farthest from their sleeping quarters. Here there should be a rack filled with choice legume hay. The sows will thus not only secure needed vitamins, calcium, and protein, but also they will get considerable exercise, instead of lying in their pens most of the time.

Indiana experiments show that too much exercise reduces the gains and the feed efficiency of growing and fattening pigs.[155] Pigs that were exercised by driving them one-half mile each day made less rapid gains and required slightly more feed per 100 lbs. gain than others which were confined to a small feed lot.

1442. Barrows; sows.—Up to the usual market weights, barrows make only a trifle more rapid and economical gains than do open sows. The slight difference is due to restlessness of the sows during the estrus periods. In Wisconsin and Minnesota studies the difference in average daily gains for barrows and gilts was only 0.02 to 0.08 lb. per head daily.[156]

In experiments where the yields of dressed carcass and of the various cuts from barrows and from unbred gilts have been determined, there has been no consistent difference in the dressing percentage.[157] Gilts tend to have a slightly smaller proportion of fat at a given age, which is opposite to the condition in cattle. The yield of hams is generally slightly higher for gilts, and that of bacon slightly less. In an Illinois test the meat from barrows was slightly tougher, on the average, than from gilts.[158]

In the chief pork producing regions of this country it is a common practice to fatten sows for market following the weaning of their first or second litters. In a Wisconsin trial thin sows fed a well-balanced ration gained 2.5 lbs. a day for a period of 56 days and required about the same amount of feed per pound of gain as growing and fattening pigs fed a similar ration.[159]

Many farmers follow the practice of breeding the sows at the beginning of the fattening period, as they believe this results in faster and more economical gains. In South Dakota tests in which sows were fattened for about 2 months, the average daily gain of sows that had been bred was 0.26 lb. more than for sows that had not been bred, and the feed cost per 100 lbs. gain was 77 cents less.[160] However, these advantages were more than offset by the fact that the bred sows sold for an average of 34 cents less per hundredweight.

Slaughter tests showed that the bred sows averaged slightly lower in dressing percentage, in grade of carcass, and especially in grade of bacon belly. It was concluded that the breeding of sows during the fattening period was undesirable from the standpoint of both producer and packer.

Spaying sows before fattening them is of no advantage, for unspayed sows make just as good gains.[161]

1443. Types of swine.—It is outside the scope of this book to discuss the breeds and breeding of livestock. Therefore, only certain very general statements can be made concerning the types of swine.

Extensive swine breeding investigations have been and are being conducted by the United States Department of Agriculture, in cooperation with several of the state experiment stations. The object of these experiments is to develop strains or breeds of swine that excel in rate and economy of gain and that produce the kind of carcasses that meet present-day demands better than the former lard-type hogs.

In addition to producing strains or lines of the older breeds which meet these demands better, new breeds have been developed by crossing swine of our common American breeds with the bacon breeds. Such new breeds are Beltsville

No. 1 and No. 2, Maryland No. 1, Minnesota No. 1 and No. 2, and Montana No. 1.

Experiments show that the amount of feed required per 100 lbs. gain to market weights by meat-type hogs is no greater and usually somewhat less than for the old-fashioned over-fat kind.[162]

The modern meat-type hogs meet the demand in this country for leaner but well-finished carcasses. For the production of very superior bacon, which commands a decided premium in Great Britain and some other countries, the distinct bacon breeds are preferred.

1444. Swine improvement; production records.—In order to secure the best returns from swine it is necessary to have well-bred breeding stock. The sows and boar should be carefully selected from strains of swine that excel in the following characteristics: (1) They produce good-sized litters of thrifty pigs; (2) their pigs make rapid gains and therefore usually economical gains; (3) their pigs yield carcasses that meet the present market demands.

Disposition and milk yield are also important factors to consider in selecting sows to retain in the herd. If a sow has a mean disposition or if she is careless, she may crush or injure a considerable percentage of the pigs she farrows. If a sow does not have a good flow of milk, her pigs will fail to make good gains.

A herd record should be kept in which the number of pigs farrowed and the number raised by each sow are recorded, with notations as to whether the pigs make good gains. Only gilts from the best sows, as shown by this record, should be retained for the breeding herd. To identify the pigs, they should be ear-notched or otherwise marked at birth.

Outstanding progress has been made in Denmark and certain other European countries in using production records for swine improvement. In Denmark herds of swine of approved type are designated as breeding centers.[163] To ascertain the strains which are superior in these herds, 4 pigs are selected from a litter and fed to market weights on a standard ration at a central feeding station, where a careful record is kept of feed consumed and gains made. Representative pigs from each litter are slaughtered in order to secure data on the desirability of the carcasses. This method of swine testing has also been used effectively in Canada.

Since rapid-gaining pigs usually make the most economical gains, pig-recording systems have been developed in Sweden, Great Britain, and some other countries. These are often combined with the milk-recording service for dairy herds. Under these systems the pigs are ear-notched and weighed at a definite age by an inspector. These records are used as a basis for the selection of breeding stock.

In order to promote more efficient pork production, various swine registry associations in this country have adopted a standardized "production registry" for brood sows and boars. To qualify for entry in the production registry, a sow must meet certain definite requirements, based on the number of pigs raised per litter in 2 litters and on the total weight of the litter at 56 days of age. Boars are admitted to the production registry when they have sired a certain number of sows that have qualified for the registry.

1445. Dressing percentage.—It was found in studies by the United States Department of Agriculture that the dressing percentage in winter of hogs dressed "shipper style," with heads on and without the leaf fat, kidneys, and ham facings being removed, averaged 78 per cent, based on purchase weights and for hogs in transit 12 hours after purchase.[164] The dressing percentage averaged only 74.5 per cent for hogs in transit 84 hours. It was slightly lower in summer than in winter. The dressing percentage for hogs dressed "packer style," with the head off and the leaf fat, kidneys, and ham facings removed, will be about 8 per cent less than for those dressed "shipper style."

The chief factor affecting the dressing percentage is the degree of fatness. It has been pointed out previously that when pigs are fed a limited ration during the finishing period, the dressing percentage is a little lower than in the

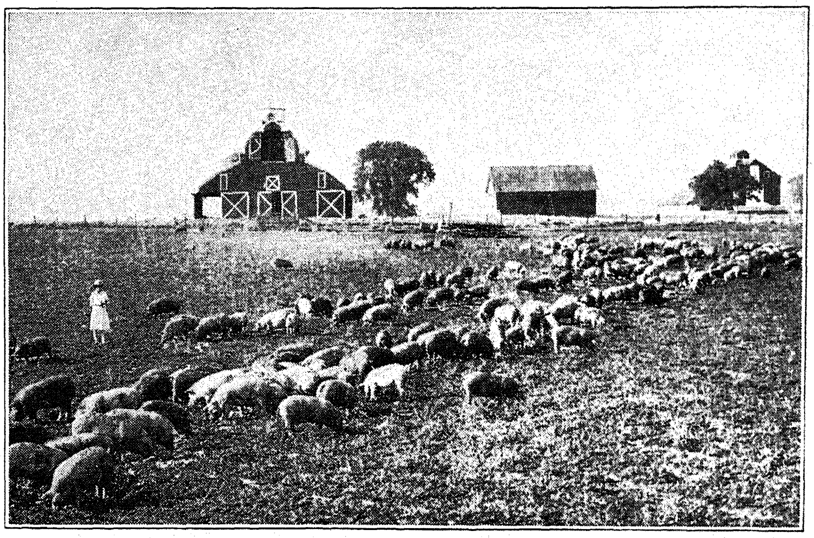
case of full-fed pigs at the same market weight. (1429)

In Ohio studies there was a low point in dressing percentage in September and October, probably due to the marketing of pigs that were not very well finished.[165] The dressing percentage then increased gradually and reached a high point in January and February.

1446. Soft pork.—Certain feeds, especially soybeans, peanuts, rice bran, rice polish, and chufas, tend to produce soft pork when fed to pigs in considerable amounts. The products from hog carcasses that are soft are undesirable from the standpoint of both the processor and the consumer, and therefore sell at a decided discount.

Lard from soft hogs does not harden at ordinary temperatures. The bacon is soft and flabby, and it is difficult to slice, even with a machine. The loins are smeary and unattractive. The hams are less affected, as they have a smaller proportion of fat. When the pork is very soft, oil will drip from hams or bacon in the smoke house, thus increasing the shrinkage. Unless the carcass is extremely soft, the meat after cooking may be just as attractive and palatable as that from a firm carcass. However, there will be more wastage in cooking, because of a greater loss of fat.

It is impossible to determine whether or not hogs will have soft carcasses by handling them when alive, as the fat is fluid at body temperature even in the case of hogs that yield hard carcasses. In sections where there is considerable trouble from soft pork, the packer usually protects himself against loss by paying a lower price for all hogs, or buys them subject to a discount if they kill soft.



FATTENING PIGS FED EAR CORN ON PASTURE

Corn is most commonly fed to swine in the form of ear corn or shelled corn.

Extensive experiments have been conducted by the United States Department of Agriculture and various experiment stations to study the soft pork problem and especially to find the extent to which softening feeds can be used without producing soft pork.[166]

These investigations have shown that the body fat which swine make from carbohydrates or protein in their food has a melting point sufficiently high to be hard and firm at ordinary room temperatures. However, fat in the feed may be converted into body fat with but little change. Therefore, when swine receive

such feeds as soybeans and peanuts, that are high in fat, much of the fat deposited in their bodies comes from this source. Since the fat in these feeds is liquid at ordinary temperatures, soft pork results if much of the body fat comes from this source.

The grains also contain fat which is liquid at ordinary temperatures and which will produce soft pork if fed in large enough amounts. However, the percentage of fat in the grains is relatively low. When pigs are fed on grain and supplements that are not high in fat, most of the body fat is therefore made from the carbohydrates, and not from the fat in the feed. Such rations hence produce firm pork.

Corn and oats, which have considerably more fat than the other grains, have some tendency to soften pork. Oats have a more marked effect than does corn, because of their higher fat content. Barley, wheat, rye, and the grain sorghums tend to produce hard pork, because of their lower fat content.

When pigs are well fattened on corn and such supplements as tankage, meat scrap, fish meal, or dairy by-products, their carcasses are sufficiently firm and hard to meet the requirements of the markets in the United States. However, for the production of the type of bacon that commands a premium in England, a harder carcass is necessary. Therefore, corn should not form too large a part of the ration when such bacon is to be produced.

Pigs that make rapid gains usually yield firmer carcasses than do pigs which have gained only slowly on the same combination of feeds. This is because fast-gaining pigs make a larger proportion of the stored fat from carbohydrates in the ration, and less comes from the fat in the feed.

1447. Preventing soft pork.—In using feeds that have a softening effect on the carcass, soft pork can be prevented when either of two methods is used: (1) The softening feed is fed only to brood sows and to young pigs up to certain weights. The pigs are then fed until they reach market weight on a ration which produces hard pork. (2) A hardening ration is fed to the pigs until they reach certain weights, and then they are fed a ration which includes only a very limited proportion of the softening feed. (**804**)

North Carolina investigations show that to produce firm carcasses pigs cannot be fed a total per head of more than 90 to 100 lbs. of peanuts (on the shelled basis).[167] The peanut feeding must start when the pigs weigh 60 lbs. or less, and after the stated amount has been fed, the pigs should be finished on a hardening ration of corn and supplements, containing 13 to 15 per cent of cottonseed meal. The gain in weight during the hardening period should be 3.5 times that during the period when peanuts are fed.

As stated in Chapter XXII, nearly one-third of the peanut acreage in this country is harvested by hogging down with growing and fattening pigs, in spite of the fact that this produces soft pork. (**839**) This is because of the cheapness of this method of producing pork.

It is also shown in Chapter XXII that more than 10 per cent of soybeans in the ration has a decided softening effect on the carcass, if continued throughout the fattening period. (**804**) The tendency to produce soft pork is reduced if pigs in dry lot weigh at least 125 lbs. when soybean feeding is begun, and those on pasture at least 75 lbs. Hogging down ripe soybeans produces soft pork. Soybean oil meal does not produce soft pork when fed in any ordinary amount.

The effects of other feeds upon the character of pork have been discussed in the various chapters of Part II. If a ration for pigs contains more than one-half hominy feed of the usual fat content, the carcasses are apt to be somewhat soft. (**708**) Too large a proportion of rice bran or rice polishings produces a marked softening effect on the carcass. (**784, 785**)

Certain feeds have much more of a hardening effect than a ration of corn and tankage. Cottonseed meal has such an effect. Therefore an excellent ration for hardening the carcasses is corn sup-

plemented by a combination of cottonseed meal and either tankage or fish meal. (818) Brewers' rice and sweet potatoes also produce firm pork, because of the very low content of fat.

1448. Production of high-quality bacon.—Consumers generally prefer bacon that has a good "streak" of lean meat, and which is firm and of fair thickness. In the United States most of the best bacon is made from the leaner pigs of the meat type. However, in Great Britain there has long been a demand for a very superior quality of bacon, marketed under the name of "Wiltshire sides."

This demand is met by pigs produced there and by importation, chiefly from Denmark, Ireland, and Canada. A Wiltshire side comprises the entire half of the dressed pig, minus the head, shanks, shoulder bone, and hip bone. All of the side, except the ham and the shoulder, is sold as "bacon."

Wiltshire sides are made from choice pigs that have proper length of body, a high proportion of lean meat, a medium covering of fat on the back (preferably 1.0 to 1.5 inches thick) and bellies smoothly finished with firm fat. Even a slight degree of softness of fat, that would not be very objectionable on our markets, will disqualify a carcass for high-quality Wiltshire sides.

Full-feeding pigs a concentrated ration throughout growth and fattening is apt to produce carcasses having too much fat and too little lean to meet the requirements for Grade A bacon carcasses on Canadian markets. It has been shown previously that the carcasses are leaner when pigs are fed liberally during early growth and then are restricted in energy intake during the finishing period. (1429)

Hand-feeding a limited ration after the pigs reach a weight of 100 to 125 lbs. is one way of reducing the energy intake. However, this requires more labor than does self-feeding. Also, the greediest pigs often get much more than their share of feed, and as a result are actually full-fed.

Recent Canadian experiments show that the desired type of carcass can be secured if sufficient very bulky feed, such as ground legume hay or wheat bran, is included in a self-fed mixture, so as to reduce the gain during the finishing period to about 1.25 lbs. per head daily.[168] Pigs thus fed may require slightly more feed per 100 lbs. gain than those which are full-fed a concentrated ration. However, this will be offset by the larger proportion of the carcasses that receive the Grade A premium on the Canadian markets.

Barley ranks above wheat or corn for the production of bacon of highest quality. It not only produces firm carcasses, but also it tends to produce a larger proportion of lean, because it has somewhat more fiber. However, when barley is the only grain in a full-fed ration, leaner carcasses are produced when the nutrient intake is reduced during the finishing period. Therefore, feeding a combination of barley and oats or adding a still more bulky feed makes leaner carcasses.

Skimmilk, buttermilk, or whey, fed in combination with grain, make excellent bacon. Such pastures as alfalfa, clover, or rape also help to produce high-quality bacon carcasses.

QUESTIONS

1. Compare the efficiency of pigs and other classes of stock as meat producers.
2. Discuss the rate and economy of gain by pigs of various weights.
3. At what weights should pigs commonly be marketed in the United States?
4. Why do swine suffer from nutritive deficiencies more frequently than do cattle, sheep, or horses?
5. Compare the ability of swine and of ruminants to digest various classes of feeds.
6. Discuss the importance of good pasture or legume hay for swine.
7. Name 5 protein supplements that provide protein of good quality for swine.
8. Name 7 protein supplements that are unsatisfactory when fed as the only supplements to swine not on pasture.
9. Discuss the amounts of protein required by swine.
10. State a common ration that is deficient in tryptophan for young pigs. How can the lack be corrected?

11. State a combination of feeds that is well adapted to self-feeding by the free-choice plan. State a combination of feeds which is not suited to free-choice feeding.
12. Discuss the use of protein supplements with the cereal grains for pigs not on pasture.
13. Under what conditions would you feed a protein supplement to pigs fed grain on good pasture? When is it more economical not to use a supplement?
14. Discuss the need of pigs for fat.
15. What is the effect of adding surplus animal fat to a ration for pigs?
16. Of what importance is the fiber content in rations for growing and fattening pigs?
17. Discuss the requirements of swine for salt.
18. State in detail the kind of rations for swine: (a) That require a calcium supplement; (b) that require a phosphorus supplement; (c) that need no calcium or phosphorus supplement.
19. What are the approximate minimum percentages of calcium and of phosphorus that swine rations should contain?
20. How can goiter or hairlessness in new-born pigs be prevented?
21. Give 3 methods of preventing anemia in suckling pigs.
22. Discuss the trace mineral needs of swine.
23. Discuss the use of simple versus complex mineral mixtures for swine.
24. State the conditions under which swine have an abundant supply of vitamin A value and the conditions under which there will be a deficiency.
25. State the same facts for vitamin D.
26. Which B-complex vitamins may be deficient in balanced rations for swine?
27. What feeds will correct a lack of: (a) Riboflavin; (b) niacin; (c) pantothenic acid; (d) vitamin B_{12}?
28. What is known about the need for unidentified vitamins by young pigs?
29. Under what conditions is it beneficial to add a B-complex supplement to rations?
30. Discuss the importance of legume hay as insurance against vitamin deficiency.
31. In what sort of ration for growing and fattening pigs would you use only 5 per cent of legume hay? In what kind of ration would you use 10 to 15 per cent of legume hay?
32. Discuss the use of other vitamin supplements for dry-lot feeding.
33. What is a trio mixture? Why are trio mixtures and similar combinations superior to tankage or fish meal as the supplement to grain for young pigs in dry lot?
34. In what different ways may a trio mixture and similar combinations be fed?
35. In what ways can the trio mixture be modified?
36. State the formula for another efficient supplemental mixture for pigs not on pasture.
37. State 2 combinations that are superior to tankage or meat scrap alone as the supplement for pigs on pasture.
38. Discuss antibiotic feed supplements for: (a) Growing and fattening pigs; (b) brood sows.
39. Would you add an arsonic supplement or a surfactant to an efficient ration that contains an antibiotic supplement?
40. Discuss hormones for pigs.
41. Discuss the water requirements of swine.
42. At what times during the year should pigs be marketed to bring the highest prices, on the average?
43. What effect may the level of feeding have on the carcasses of pigs?
44. Discuss limited-feeding vs. full-feeding of pigs: (a) On pasture; (b) in dry lot.
45. What results have been secured in experiments in which self-feeding of pigs has been compared with hand-feeding: (a) In dry lot; (b) on pasture?
46. What grains should commonly be ground for swine?
47. What feeds for swine may be improved by soaking?
48. Under what conditions may it be desirable to feed concentrates to pigs in the form of a slop?
49. Discuss: (a) Cooking feed; (b) pelleting feed; (c) use of feeding platforms.
50. How can the bad effect of very hot weather on swine be prevented?
51. Discuss: (a) Shelter for swine; (b) exercise; (c) barrows vs. gilts; (d) fattening sows.
52. What type of swine best meets present consumer demands in this country?
53. What methods have been used in Europe for improving the quality of swine carcasses and increasing the efficiency of production?
54. What is the production registry for swine?
55. What is the average dressing percentage of swine in winter?

56. Discuss the soft pork problem, stating the feeds that produce soft pork and describing the extent to which peanuts can be fed to pigs without producing soft pork.
57. Discuss the special requirements for the production of choice bacon to be marketed as "Wiltshire sides."

CHAPTER XXXV

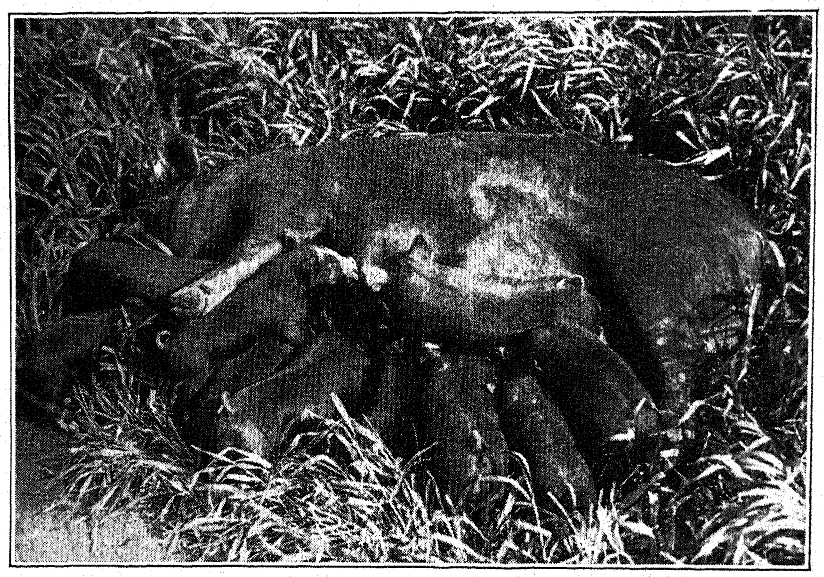
FEEDING AND CARE OF SWINE

I. Pasture for Swine

1449. Importance of good pasture for swine.—When plenty of good pasture is provided for swine throughout the growing season, pork can usually be produced at much lower cost than when swine are kept in dry lots. The importance of pasture in keeping swine thrifty and preventing nutritional deficiencies has been emphasized in the previous chapter. (1383)

Not only does good pasturage furnish digestible nutrients at low cost, but still more important, it provides insurance against any deficiency of vitamins. In addition, the best pasture crops are rich in protein of fairly good quality and they are high in calcium.

Good pasture is especially important for brood sows and boars and for young pigs. Sows that are raised entirely in dry lot are apt to produce unsatisfactory litters, even when fed rations that would be satisfactory if the sows had been on pasture part of the time. (1384) Similarly, fall pigs do better during the winter when they get a good start on pasture before they are confined to dry lot.



Every Litter Needs Good Pasture

Nothing is more important in swine raising than furnishing good pasture just as early as possible for the brood sows and their litters.

Another advantage of keeping swine on pasture is that it builds up soil fertility, because the manure is well distributed over the field. When swine are kept in small unpaved hog lots, often but little use is made of the manure and much fertility is wasted.

Because of the many advantages and the great economy of pasture for swine, the largest net returns can usually

be secured only when an abundance of first-rate pasture is provided during as much of the year as is possible.

In the southern states good pasture can even be provided during all or most of the winter. In the North there should be good pasture for the brood sows and their litters in the spring; for the growing and fattening pigs from weaning time until market or until frost kills the crop; for the brood sows and boar throughout the growing season; and especially for any fall pigs.

It must be borne in mind that good pasture means not only pasture which furnishes plenty of palatable feed, but also pasture that is not contaminated with round worms and other swine parasites. It is emphasized later in this chapter that to prevent serious trouble from internal parasites, a system of swine sanitation should be followed, in which pigs are on clean pasture throughout the season, instead of being kept in filthy hog lots. (1491)

Occasionally, statements are made that pigs fattened on pasture do not yield as desirable carcasses as those finished in dry lot. Experiments have shown, however, that when pigs are properly fattened on pasture by feeding a liberal amount of grain in a balanced ration, the carcasses are fully equal to those from dry-lot feeding.[1]

Sometimes a plan of producing pork is advocated in which no pasture whatsoever is used, but instead all swine are confined to inside pens with access to outside paved lots. As has been emphasized in the preceding chapter, it is difficult to prevent nutritional deficiencies when swine never have access to pasture. (1384) The use of pasture, especially for brood sows and young pigs, therefore seems decidedly preferable to keeping swine continuously on concrete. When pigs are fed in dry-lot from weaning time to market, it is important that they first get a good start on first-rate pasture.

1450. Various pasture crops.—The choice of pasture crops for any particular section will depend primarily on the soil and climatic conditions. Those pasture crops are best for any locality which give high yields of palatable, nutritious forage over a long season, at a low cost for growing the crop. Detailed information is given in Chapter XIII concerning pastures and pasture improvement and management. The many different crops suitable for pasture are discussed in other chapters of Part II.

Wherever they thrive either alfalfa or Ladino clover ranks first as a pasture crop for swine. They provide excellent forage over a longer season than most other forage crops, and are very rich in protein, calcium and vitamins. A mixture of these legumes with a moderate amount of grass may be equal to the legume alone, and endure longer in the pasture.

Red clover also is excellent for swine pasture, but generally provides less feed in midsummer. Alsike clover is suitable for soils too wet or too acid for red clover. White clover is important in mixed and permanent pastures, for it greatly improves grass pasture. Sweet clover may be used in districts where it thrives better than alfalfa or red clover, but in other sections it is decidedly inferior to them.

Lespedeza is one of the most valuable pasture crops in the South. Soybeans furnish good forage for only a rather short season and are therefore less valuable for pasture than alfalfa, Ladino clover, or red clover, where the latter thrive. Cowpeas are a useful pasture crop for poor soil in the South, but are excelled by soybeans on good soil.

Rape is the best single annual pasture crop for swine where it thrives, and is nearly equal to alfalfa or red clover in value per acre. If not pastured too heavily, early-sown rape will furnish good forage from early summer until late in the fall, for the plants are not killed by ordinary frosts. In the northern-most states a combination of rape with oats or barley, or with oats and peas, may be slightly superior to rape alone.

Permanent grass pasture, such as bluegrass, furnishes good forage in spring and in autumn, but often supplies little feed in mid-summer. Other pasture should therefore be provided for this season. Bromegrass and orchard grass

furnish pasture over a longer season than bluegrass, and much more forage in midsummer. However, they are more valuable when combined with a suitable legume.

Pigs on grass pasture require a somewhat greater amount of protein supplement than those on such protein-rich pasture crops as alfalfa, clover, or rape. Sudan grass is a satisfactory pasture crop where the climate is too dry for better pastures.

Winter cereals provide excellent late fall and early spring pasture in the northern states. In the South first-rate pasture can be furnished during much of the winter by winter cereals or by crimson clover and rye grass.

1451. Essentials on pasture.—Swine on pasture should be provided with an abundant supply of fresh water and with shade. Salt should always be furnished, except possibly when tankage, meat scrap, or fish meal is fed as the only supplement. (1398)

It is often necessary to ring hogs to prevent serious damage to a pasture by rooting. Swine that are fed well-balanced rations are much less apt to root than are dissatisfied hogs fed an inefficient ration, but the feeding of a good ration is no insurance against rooting.

Sometimes it is not necessary to ring spring pigs which will be sold in the fall at the close of the pasture season, for they are less apt to root than are older hogs. However, the pasture lots must be watched closely, and if the pigs start to root badly, it will be necessary to ring them at once, especially if they are on a permanent pasture, such as alfalfa or bluegrass. Even if fed good rations, pigs are apt to begin rooting after hard summer or fall rains, in order to get the earth worms which then come close to the surface of the ground. This is not surprising, since in its natural state the hog gained its living largely by rooting. On annual crops, such as rape, it is not usually necessary to ring pigs if they are fed well-balanced rations.

1452. Value of pasture in pork production.—The importance of good pasture in increasing the net returns from swine is well shown by 1,419 yearly cost accounting records of pork production on Minnesota farms.[2] On farms where swine had good pasture (legumes, rape, or rape combined with small grain), an average of only 486 lbs. of feed (including that eaten by the breeding herd) were required per 100 lbs. of hogs marketed. On farms where the swine had no pasture, the feed requirement was 522 lbs., and on farms where the only swine pasture was timothy or bluegrass, it was 509 lbs.

The difference was even greater in the net return over cost of feed per 100 lbs. of hogs marketed. This was $1.70 per 100 lbs. on the farms with good swine pasture, but only $1.22 on the farms with no swine pasture and $1.37 for those with grass pasture for swine. The net return over cost of feed was therefore 39 per cent greater where good pasture was provided than where the hogs were kept in dry lot.

1453. Pasture vs. dry lot for growing and fattening pigs.—Though good pasture is most important for brood sows and young pigs, numerous experiments have shown that it also has a high value for growing and fattening pigs, even those that have gotten a good start on pasture.

The advantage from pasture-feeding in comparison with feeding an efficient ration in dry lot is shown by the results secured in 40 experiments.[3] In each trial one lot of pigs was full-fed corn and a suitable supplement on good pasture from shortly after weaning until the pigs reached market weight. Another lot was fed in dry lot on corn and an efficient modern supplement which contained ground legume hay.

The pigs on pasture gained 1.43 lbs. per head daily and required 359 lbs. concentrates per 100 lbs. gain. Those fed the efficient ration in dry lot gained nearly as rapidly (1.40 lbs. a day), but they consumed 399 lbs. of feed per 100 lbs. gain. Thus, 40 lbs. more concentrates, or 11 per cent more, were required per 100 lbs. gain by the dry-lot pigs. The greater part of this additional feed was expensive protein supplement, for pigs

in dry lot need much more protein supplement than do pigs on good pasture.

In the earlier experiments, comparing pasture-feeding with dry-lot feeding, there was a considerably greater difference in the results. This was because the dry-lot pigs were fed such a ration as corn and tankage. As has been emphasized in the preceding chapter, this sort of ration is much less satisfactory for pigs in dry lot than efficient modern rations that include legume hay and a suitable combination of protein supplements. (**1418–1420**)

The opinion is sometimes held that pigs which have been raised to a weight of 100 to 150 lbs. on pasture will make more rapid and economical gains during the final fattening period if they are finished in dry lot, where they get less exercise. However, in New York experiments conducted during 6 summers to study this method, the gains were about as rapid and slightly more economical when the pigs were kept on good pasture until they were ready for market.[4] Keeping pigs on pasture until they are ready for market saves the labor of cleaning out manure from the hog barn.

When pigs are full-fed grain and supplement on good pasture, an acre of pasture should provide enough forage for 15 to 20 pigs from weaning time to the end of the pasture season. Pigs fed only a limited amount of concentrates need more pasture.

If pasture feeding is compared with an efficient dry-lot ration, such as corn and a trio-type supplemental mixture, an acre of good pasture for full-fed pigs will usually save 300 to 500 lbs. grain and 450 to 700 lbs. supplement.

The stand of alfalfa or Ladino clover is injured by continuous close grazing. Therefore, if one wishes to maintain the stand for several years, it is best to provide a sufficient area of these crops so that considerable forage will grow up to be cut for hay once or twice during the season. Alfalfa should carry at least 8 to 10 full-fed pigs per acre throughout the summer with no danger to the stand. (**466**)

II. The Breeding Herd

1454. Selecting the brood sows and boar.—For efficiency in pork production, it is necessary, first of all, to have breeding stock of the right kind. The sows and boar should be of the proper type and conformation to produce finished hogs that meet the market demands. Also, they should be selected from strains of swine that excel in rapidity and economy of gains. Fully as important as these essentials, is the prolificacy of the sows and their ability to raise good-sized litters of pigs.

It costs nearly as much to feed and care for a sow that raises a litter of only 3 to 5 pigs to weaning age as a sow that raises 7 or 8 pigs or more. Therefore, to reduce the cost per pig at weaning time, the sows must have large litters of thrifty pigs and also be good mothers, so they will raise nearly all of the pigs that they farrow.

To build up an efficient herd the pigs should be ear-notched or otherwise marked, and breeding records should be kept. The sows that have proven to be unproductive can then be culled from the herd and replaced by gilts from the best sows. These will be the ones that are good mothers and raise large litters of pigs of good type which make rapid gains in weight. Such pigs produce pork much more economically than do those which gain slowly.

1455. Proper feed and care necessary for profits.—In securing a good profit from hogs nothing is of greater importance than proper feeding and care of the brood sows and boars. Every year thousands of farmers are grievously disappointed at farrowing time by seeing their possible profits vanish when the sows produce unsatisfactory litters.

Either the number of pigs in the litters is small, or the pigs are so weak that many die or survive only to become unprofitable runts. In most cases such results are due to lack of proper feed and care. Yet the needs of brood sows are relatively simple and easily met.

The most important essentials in the feeding and care of brood sows are: (1)

Efficient rations that fully meet their nutrient requirements; (2) rations that are laxative, instead of constipating; (3) the right amount of feed—not too much or the sows will get too fat; (4) plenty of exercise; (5) comfortable, sanitary quarters, with guard rails or pig brooders in the pens to protect the young pigs; (6) freedom from lice and worms.

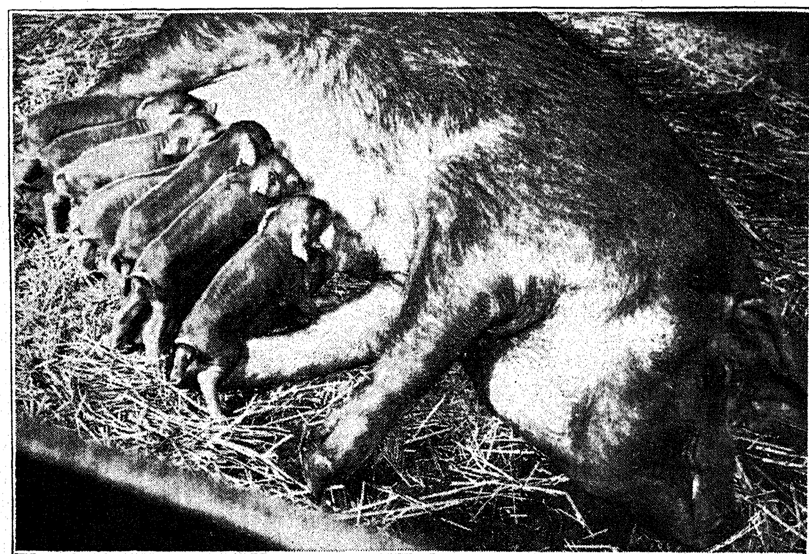
1456. Rations for brood sows.—The nutrient requirements of brood sows have been discussed in detail in the previous chapter. Further information is given in articles which follow concerning their special needs for protein, minerals, vitamins, and amount of concentrates. The Morrison feeding standards (Appendix Table III) show the amounts of dry matter, digestible protein, total digestible nutrients (or net energy), calcium, phosphorus, and carotene that should be provided per head daily for pregnant gilts, for pregnant older sows, and for brood sows nursing litters.

In Appendix Table VII will be found examples of well-balanced efficient rations for pregnant sows and for those which are nursing litters. Modifications can readily be made in these rations to adapt them to local conditions.

Corn or other grain ordinarily forms most of the ration for sows during pregnancy and also during the suckling period. In addition, sows should be fed supplements to provide plenty of protein, calcium, phosphorus, and vitamins.

As shown later, whether or not a protein supplement will be needed in addition to legume hay and grain for wintering pregnant sows will depend on the age of the sows, on the quality of the hay, and on the proportions of hay they actually consume. (1460) Sows that are suckling pigs should always be fed a protein supplement in addition to grain and either pasture or legume hay, as they need a considerably larger proportion of protein. A supplement should be used that provides protein of proper quality to correct the deficiencies in the proteins of the cereal grains.

The mineral and vitamin requirements of swine have been discussed in detail in the preceding chapter. When



ABILITY TO RAISE GOOD-SIZED LITTERS ESSENTIAL

For economical pork production, the sows must have the ability to raise good-sized litters of thrifty pigs.

sows are not on pasture, an abundance of vitamins is best assured by including at least 10 to 15 per cent of good-quality, field-cured legume hay in the ration. The vitamin needs are amply met by good pasture. If sows kept in dry lot cannot have plenty of legume hay of satisfactory quality, a B-complex vitamin supplement may be needed. (**1416**)

1457. Grains and grain substitutes for brood sows.—Because of its cheapness, corn is the chief grain fed to sows throughout the corn belt. Owing to the poor results when corn is unwisely fed to brood sows without proper supplements, the statement is sometimes made that corn should not form over one-third to one-half the ration for brood sows, as it is "too fattening." However, experiments have shown clearly that excellent results are secured when corn is the only grain, if it is properly supplemented and provided the allowance is strictly limited to the amount needed to keep the sows in thrifty condition without becoming too fat.

For example, in 3 Wisconsin trials a simple ration of ear corn, alfalfa hay fed in a rack, and 0.3 lb. tankage was slightly superior for wintering pregnant gilts to a more complex ration having only 35 per cent corn.[5] This mixture was 35 lbs. ground corn, 30 lbs. ground oats, 30 lbs. wheat middlings, and 5 lbs. tankage. The cost of feed per sow was 30 per cent less on the simple ration.

The other grains are satisfactory substitutes for corn in feeding brood sows. The relative values of the various grains for swine are stated in Chapters XX and XXI. Ground wheat is fully equal to corn in value, while ground barley or grain sorghum is worth slightly less per pound. Ground oats are excellent as part of the grain for brood sows. However, if oats form more than one-third to one-half of the grain allowance, a little more feed will be needed to keep the sows in proper condition than when corn is the chief grain.

1458. Grain alone or grain and minerals unsatisfactory.—Even when sows have been on good pasture during summer, a winter ration of grain alone or grain and minerals is very unsatisfactory. This is true even if the grain is yellow corn, which supplies considerable carotene. In the case of gilts, such a ration is apt to produce disastrous results, for their pigs are often weak and unthrifty and some may be dead at birth. Also, when sows are fed inadequately during pregnancy, there is sometimes a tendency for them to kill and eat their young pigs.

The poor results from feeding a ration of only corn and minerals to pregnant sows are shown by Indiana experiments.[6] Gilts wintered on only yellow corn and bone meal farrowed pigs that were dead or were so weak that they died within a day. The results were somewhat better on a combination of yellow corn, oats, and bone meal, but 36 per cent of the pigs were dead at birth or died within 3 days. On the other hand, when 5 per cent of meat scrap was added to the ration, the sows farrowed twice as many pigs, with only 13 per cent that were born dead or died within 3 days. This ration would have been still further improved by the addition of legume hay.

The results have likewise often been disastrous in experiments where other grains, such as barley, grain sorghum, or a combination of corn and oats, have been fed alone or with only mineral supplements to pregnant sows.[7]

Sows that have been on first-rate pasture throughout the growing season usually have good stores of vitamins and minerals in their bodies when winter starts. Sometimes mature sows may therefore produce fairly satisfactory litters when wintered until farrowing time on only yellow corn or corn and oats, if they are in a pasture lot where they can get a little green feed even in winter and where they are protected against a lack of vitamin D by exposure to sunlight.[8] However, such a method of feeding is unsafe for pregnant gilts and cannot be recommended even for mature sows.

1459. Importance of legume hay in winter rations.—The previous chapter has stressed the great importance of including good-quality legume hay as in-

surance against vitamin deficiencies in rations for brood sows not on pasture. (1383–1384) Legume hay excels in so many respects and also is such a cheap feed that a special effort should be made to provide it for sows in winter. Good-quality field-cured legume hay not only usually prevents any lack of vitamins, but it is also important as a source of protein and of calcium.

For insurance against vitamin deficiencies, a safe rule is to see that legume hay forms at least 10 per cent, and preferably 15 per cent, of the ration for sows in winter. Pregnant sows may well be fed all the legume hay they will eat in addition to a limited allowance of grain.

When choice, leafy alfalfa hay is used, sows will usually eat a sufficient amount if it is fed uncut in a simple slatted rack, preferably with a cover to keep out snow and rain. As stated later, this rack and also the feed troughs should be put at some distance from the hog barn or colony house, so the sows will secure plenty of exercise.

Red clover hay is usually less palatable to sows than alfalfa, and consequently they will often eat relatively little of it when fed uncut in a rack, even if the allowance of concentrates is restricted. Whenever the sows fail to eat enough legume hay, it should, if possible, be chopped or ground and mixed with the concentrates. The hay may be chopped at small expense by running it through a silage or hay cutter, preferably equipped with an alfalfa screen. If no cutter is available, the leaves and chaff which accumulate where the hay is pitched from the mow may be gathered up and mixed with the concentrates. To get the sows to clean up such chaff it may be necessary to feed the mixture as a slop.

Information is given in Chapter XVI concerning the composition and value of the various kinds of legume hay. Alfalfa excels clover, because it is richer in vitamins, protein, and calcium, as well as being liked better by swine. Soybean hay, lespedeza hay, cowpea hay, and other kinds of legume hay are satisfactory substitutes for alfalfa.

Mature sows are sometimes wintered on alfalfa hay without any grain or other concentrates, but this is inadvisable, for they will then not make the desired gains in weight during pregnancy. Also, although the cost for feed up to farrowing time will be low, Pennsylvania experiments show that it will later be necessary to feed them with great liberality on concentrates to provide even a fair milk flow for their pigs.[9] This will offset the saving in concentrates before farrowing.

1460. Legume hay as the only protein supplement.—For wintering pregnant sows a year old or more, a ration consisting of only grain, legume hay, and a mineral supplement is satisfactory, if the hay is of excellent quality. When leafy, palatable alfalfa hay is fed to such sows, they will generally eat a pound or more per head daily, if the allowance of grain is strictly limited. Under such conditions there may be little or no advantage in adding tankage or similar protein supplements to the ration throughout the winter.[10] When the sows do not eat so much hay or if it is of only fair quality, then a protein supplement should be added. This is especially important during the last 2 or 3 weeks before farrowing, when the growth of the unborn pigs is most rapid.

In the case of pregnant gilts, a small amount of such a protein supplement as tankage, fish meal, soybean oil meal, or skimmilk had best be added to a ration of grain and legume hay, unless the hay is of choice quality and unless the gilts are forced to eat enough hay by mixing ground or chopped hay with the grain.

In Michigan experiments the results were satisfactory when both mature sows and gilts were wintered on a mixture of 2 parts ground corn or corn and oats and 1 part of ground choice-quality, second-cutting alfalfa hay.[11] Some of the hay was also fed unground in a rack and a mineral mixture was supplied to furnish additional calcium and phosphorus. The results were about as good on this home-grown ration as when 5 per cent of tankage was included in the mixture in place of the alfalfa hay.

In other Michigan trials the results were as satisfactory when sows a year old or older at breeding time were wintered on a limited amount of corn plus good alfalfa hay fed in a rack, as when they were fed a mixture of ground corn and ground hay.[12] With gilts, there was some advantage in forcing them to eat a goodly proportion of alfalfa hay by feeding a mixture of 2 parts of ground corn and 1 part of ground hay.

In 4 Wisconsin trials in which pregnant gilts were wintered on a limited amount of ear corn, with alfalfa hay fed in a rack, there was an appreciable advantage from feeding 0.3 lb. of tankage per head daily in addition.[13] The gilts fed tankage not only made somewhat larger gains, but also the average weight of the pigs at birth and the proportion of vigorous pigs were slightly greater. When credit was allowed for the greater gains, the feed cost per head daily was a trifle less for the gilts fed tankage.

When barley, oats, wheat, or grain sorghum is fed instead of corn, there will be somewhat less advantage in adding a supplement such as tankage to a ration of grain and legume hay. This is because these grains are considerably higher in protein.

Legume hay is not very satisfactory as the only protein supplement to grain for brood sows while they are nursing their litters. This is because such a ration does not supply enough protein or protein of sufficiently good quality for high milk production by sows.

1461. Protein supplements for brood sows.—Protein supplements of animal origin, such as tankage, meat scrap, dairy by-products, and fish meal, are of especially high value for brood sows, just as they are for growing and fattening pigs. Ideal winter rations for pregnant sows are combinations of grain and legume hay, along with small amounts of these efficient protein supplements.

Tankage was just as satisfactory as a mixture of protein supplements for sows during pregnancy and the suckling period in Indiana trials.[14] Only 5 per cent of tankage supplemented corn effectively.

If skimmilk or buttermilk is available for the sows, there is no better ration than grain and legume hay, plus 4 to 6 lbs. of either of these dairy by-products per head daily. There is no need whatsoever of adding purchased concentrates to such a ration, unless perhaps a little wheat bran or linseed meal shortly before farrowing, to keep the sows in a laxative condition.

Whey is relatively low in protein, but the protein it does contain is of such high quality that a ration of whey, grain, and legume hay is satisfactory for sows. If legume hay is not fed, a small amount of a feed like linseed meal, wheat middlings, or wheat bran should be added to a ration of grain and whey, especially if the grain is corn.

Soybean oil meal is an excellent protein supplement for brood sows. However, it has been shown previously that when sows are kept in dry lot for a long time, nutritional deficiencies are more apt to develop on a ration of corn, soybean oil meal, and minerals, than when an animal by-product feed is included. (1384) As has been stated, such trouble can usually be prevented by including at least 15 per cent of good alfalfa or other legume hay in the ration. Peanut oil meal, peanuts, or cooked soybeans can be used in the same manner as soybean oil meal.

Such supplements as wheat middlings, wheat bran, and linseed meal are fairly satisfactory when the sows eat a considerable amount of good legume hay.[15] However, it is best to feed in addition a small allowance of one of the more efficient protein supplements. If sows have been on excellent pasture during summer, they may produce normal litters when fed only grain and such a supplement as wheat middlings or linseed meal during pregnancy. However, feeding such a ration is unsafe, for the results may be poor, even under these conditions. Feeding this kind of a ration to sows kept continuously in dry lot produces disastrous results.[16]

1462. Animal by-products as the only supplements.—Except from the standpoint of vitamins, such animal by-products as tankage, fish meal, or skim-

milk are ideal protein supplements for brood sows. Therefore, if the sows have been on good pasture during the summer and fall and if they are out in the sunshine during the winter, they will usually produce satisfactory litters when fed only grain and such supplements during the winter.

However, it is much safer and also usually cheaper to feed sows some well-cured legume hay in addition. This will insure their receiving sufficient vitamins and will help prevent constipation. As a result, the pigs will often be stronger and more thrifty than when no legume hay is supplied. Also, the addition of legume hay to the ration will generally reduce the feed bill for wintering the sows.

1463. Roots or tubers; silage.—The experiments reviewed in Chapter XIX show that roots are not a satisfactory substitute for legume hay in feeding brood sows. (**634**) This is because they are low in protein, calcium, and phosphorus; they supply little or no vitamin D; and with the exception of carrots, sweet potatoes, and yellow rutabagas, they are deficient in carotene. When it is economical to do so, roots or tubers can be substituted for part of the grain in feeding brood sows.

Corn silage is not usually considered a satisfactory feed for brood sows, for they leave most of the forage and eat the grain. However, in recent Indiana trials brood sows produced satisfactory litters when wintered on well-eared corn silage with protein, mineral, and vitamin supplements.[17]

Alfalfa or other legume silage can be used instead of legume hay as a vitamin supplement for swine. But legume silage does not usually have enough vitamin D to be an effective vitamin D supplement. It is therefore generally better to include good-quality, field-cured legume hay in winter rations for swine.

1464. Minerals.—Brood sows should always be provided regularly with salt. (**1398**) The best plan is to let them have access to it in a suitable box, where they can take what they wish. In an Iowa test various lots of yearling gilts, wintered on rations which included some tankage, ate from one-twentieth ounce to one-fourth ounce per head daily.[18]

Whether or not it will be beneficial to supply any mineral supplement other than salt for brood sows will depend entirely on the ration that is fed, as has been emphasized previously. (**1397**) In sections where there is trouble from goiter, or hairlessness, in new-born pigs, iodine should always be supplied the sows during at least the last 12 weeks of pregnancy. (**1402**)

When sows are fed such animal by-products as skimmilk, tankage, meat scrap, or fish meal and in addition are on pasture or are supplied with plenty of well-cured legume hay, there is generally no need to add other mineral supplements to provide calcium and phosphorus. This is shown by Wisconsin experiments in which young gilts were raised from shortly after weaning on an ordinary well-balanced concentrate mixture of corn, oats, wheat middlings, linseed meal, tankage, and salt, and continued on the same mixture during pregnancy.[19] In summer the gilts were on good pasture and in winter they were fed well-cured alfalfa hay in a rack. Other lots of gilts were similarly fed each year, except that either 2 lbs. of steamed bone meal or 2 lbs. of ground limestone were mixed with each 100 lbs. of the concentrates. There were no benefits whatsoever from adding these mineral supplements to the ration, because it already had plenty of calcium and phosphorus.

If a ration is used which is low either in calcium or phosphorus, it is very important to add a supplement that will correct this lack. Unless this is done, the sows may themselves suffer from the deficiency, and also they are apt to produce unsatisfactory litters.[20] When sows have been on first-rate pasture in summer, they may sometimes have satisfactory litters even if fed a ration low in calcium or phosphorus.[21] However, this is risky, as the results are apt to be poor.

1465. Amount of concentrates for pregnant sows.—It is just as important not to overfeed pregnant sows as it is to feed them a well-balanced ration. If they become too fat, they are apt to have weak pigs, and they may be so restless and clumsy at farrowing time that many of the pigs are killed. When sows are too fat at breeding time, they may even fail to conceive. On the other hand, a sow which is too thin lacks the reserve nutrients necessary to nourish her pigs properly before and after birth.

A mature sow which is in vigorous, active condition at the beginning of the breeding season in the fall should be fed so as to gain 75 to 85 lbs. by farrowing time in the spring. This will about cover the loss in weight which will occur at farrowing and while she is nursing her pigs. More of this gain should be made during the last 4 to 6 weeks of the gestation period than during the first part, for most of the growth of the unborn litter occurs then.

Gilts should gain 100 to 125 lbs. from breeding time to farrowing, or a little less than 1 lb. per head daily.

If mature sows are fed plenty of legume hay, about 1.00 to 1.25 lbs. of concentrates daily, per 100 lbs. of live weight, will be sufficient during the first 10 to 12 weeks, and from 1.25 to 1.50 lbs. during the last 4 to 6 weeks of the gestation period. Sows will eat much more feed than this if it is supplied, and they will usually squeal lustily for a more liberal allowance.

One must therefore not pay any attention to their desires, but feed only enough to keep them at the proper weights and in the desired condition. It pleases an experienced hog raiser to see his sows industriously hunting for the last grains of corn, for he knows that they are securing the exercise which is so essential for a good pig crop. Furthermore, he knows that his feed bill will be much less than if he had allowed mistaken generosity to rule in feeding the sows.

Yearlings and especially gilts should receive more concentrates in proportion to their live weight, in order to provide for their growth. An average allowance of 1.3 to 1.6 lbs. concentrates daily per 100 lbs. live weight in addition to legume hay will usually be plenty for yearlings, and 1.5 to 2.0 lbs. daily per 100 lbs. live weight for gilts.

In a recent Illinois trial the farrowing results were better when either gilts or older sows were fed about 4.5 lbs. per head daily of a concentrated ration during gestation, than when they were either fed more or fed only 3.0 lbs. a day.[22] Wisconsin studies indicate that sows fed a somewhat limited ration after breeding may farrow slightly more pigs per litter than those which are fed too liberally.[23]

When a number of sows are kept on the farm, it pays to sort them into two or more lots, depending on age, condition, and disposition. The amount of feed for each lot can then be regulated so that all the sows are kept in the proper condition.

1466. Methods of feeding brood sows.—Pregnant brood sows are ordinarily hand-fed the amount of concentrates they need. Occasionally, they are fed by means of a self-feeder. Chopped or ground legume hay or some other bulky feed, such as oat mill feed, then must be mixed with the grain or other concentrates, so that the sows will not eat too much concentrates and get too fat.

A mixture for self-feeding to pregnant gilts should contain 25 to 40 per cent of hay or other bulky feed, and for older sows the percentage should be greater. Thus, in Nebraska trials mature pregnant sows were wintered successfully by self-feeding a mixture of 3 parts by weight of chopped alfalfa hay and 1 part of ground corn.[24] It is often necessary to change the proportion of hay at intervals during the winter, so the sows will keep in the desired condition.

In some experiments the results have been satisfactory when pregnant sows have been self-fed suitable mixtures, but in other tests hand feeding has been decidedly preferable.[25] Generally, the amount of feed consumed has been appreciably greater when sows have been

self-fed, and often the litters have been a little less satisfactory.

In Texas experiments in which various methods of feeding brood sows were compared, excellent results were secured when sows were fed the entire daily allowance in the morning at one feeding, instead of feeding them twice a day, as is usual.[26]

If sows waste considerable of a fine concentrate mixture when fed dry in a trough, the wastage may be prevented by pouring water on the mixture in the trough. In very cold weather, pouring warm water on the concentrate mixture in this manner or feeding warm slop induces the sows to take more water than they would otherwise.

1467. Exercise; shelter.—It has already been stressed in this chapter that sows should be on good pasture during as much of the year as possible. When pasture is not available, they should be induced to take plenty of exercise. In the corn belt a common practice in the fall is to turn the brood sows into the corn fields after the corn has been gathered, to pick up any scattered ears. This not only provides an abundance of exercise but also utilizes feed that would otherwise be wasted.

During the winter it is a good plan to feed the sows at some distance from their sleeping quarters. If there is at this place a rack with choice legume hay, the sows will make many trips back and forth each day. When sows are fed ear corn and the allowance is properly limited, they will spend considerable time searching for the last kernels, and the longer they can be kept on their feet, the better it is for their health. If a ground concentrate mixture is fed, it is often a good plan to scatter a little shelled corn, whole oats, or sheaf oats on the ground for the sows to work over. Sows heavy in pig should not be compelled to plow through snowdrifts, but paths should be made for them. Ashes or sand should be sprinkled on icy places, else they may slip and wrench themselves, which may result in abortion.

The benefits from letting sows have access to an outside lot during winter are shown by Indiana and Kansas tests.[27] Sows fed poor rations produced better pigs when allowed exercise and access to dirt in outside lots than when confined inside. In an Indiana trial gilts allowed to roam in a pasture field during winter produced more vigorous pigs than did others kept in a small lot. The beneficial effects in these trials may have been largely due to the exposure to sunlight, to the sows getting minerals by eating dirt, and to their securing a little needed green feed, rather than to the exercise alone.

The shelter requirements for the various classes of swine have been discussed in Chapter XXXIV. (**1440**)

1468. Summer care of brood sows.—If good pasture is provided, the problem of feeding brood sows in summer after the spring litters are weaned is easily solved. Where sows raise but one litter of pigs a year, they need little or no concentrates in summer, if they are on such first-class pasture as alfalfa, clover or rape. Grain should be fed if needed to keep the sows in thrifty condition, and in any event they should get some grain for 2 or 3 weeks before breeding time in the fall.

On such protein-rich pasture, only a small amount of protein supplement is needed to balance the ration, even when corn is the grain fed. For example, dry sows on alfalfa, clover, or rape pasture will do well on corn with no more than 4 to 5 per cent by weight of tankage, or on equal weights of corn and either skimmilk or buttermilk. When barley, oats, or wheat is fed, little or no supplement is needed if the pasture is good.

Where sows raise two litters a year, they will need more concentrates in addition to pasture, because of the added drain on their bodies. They should be fed so as to make about the same gains as recommended for sows in winter.

1469. The breeding season.—Sows are in the best condition for breeding when they are not fat, but are gaining in weight. About two weeks before breeding starts, the sows should be "flushed," just as in the case of ewes. (**1302**) This means increasing their feed

so they will gain 0.50 to 0.75 lb. a day. It is believed that sows thus treated are more apt to have large litters, and also to come in heat more promptly and to become pregnant from the first breeding.

The ration at this time should be similar to that fed during the gestation period and should contain a protein supplement. If possible, the sows should always be on pasture at this season.

Sows usually remain in heat about 2 to 3 days, and if not bred will return in heat at intervals of about 21 days.

1470. The boar.—The feed and care of the boar do not differ materially from that of the sows. The boar should be kept in thrifty condition, neither too fat nor run down in flesh, as either extreme may injure his breeding powers. In summer he should be kept in a lot where there is good pasture, and in winter he should have the freedom of a paddock of sufficient size so that he will get abundant exercise. A good plan is to have a small colony house for shelter at one end of the lot, and to feed the boar at the other end.

Although the safest plan is to see that boars can get plenty of exercise in outside lots, in a recent Nebraska experiment boars kept for 3 successive generations in a barn with little room for exercise, were fertile and sired normal litters.[28] However, they were fed an excellent ration, including alfalfa hay, a B-complex vitamin supplement, and irradiated yeast to supply vitamin D. Also, they were never allowed to become too fat.

The most common mistake made in feeding boars is to overfeed them and get them so fat that their breeding powers are seriously injured. Except during the breeding season, when more feed is required, about 1 lb. of concentrates daily per 100 lbs. live weight is sufficient in summer for fairly mature boars on good pasture. A little more concentrates will be needed in winter. Young boars should receive sufficient feed to keep them growing thriftily.

Two weeks before the breeding season starts, the ration should be increased somewhat, so the boar will be gaining in weight when service begins. The amount to be fed during the breeding season will depend on how much the boar is used. In general, he should be fed enough to prevent his losing much weight. Many breeders prefer not to feed much corn to boars at this time, but to use instead concentrate mixtures made up of other grains and a considerable proportion of protein supplements, such as wheat middlings or bran, linseed meal, tankage, and chopped legume hay.

A boar should not be used for breeding until he is 8 months of age, and then he should preferably not breed more than one sow a day and 15 to 20 in a season.[29] Yearlings and older boars should be capable of breeding 25 to 45 sows, if the services are well distributed. In breeding gilts or small sows to a mature boar, a breeding crate can be used to advantage.

1471. Gestation period; breeding studies.—The average gestation period of sows is usually given as 112 to 115 days. The length of the gestation period is not affected by the age of the sow, her size, or feeding liberal or scanty rations.[30]

The boar probably does not have any appreciable influence on the number of pigs in the litter, unless he is approaching sterility. On the other hand, he does have an influence on the number of pigs his daughters produce.

A sow that produces a small number of pigs in her first and second litters will tend to have a small number in subsequent litters. The second litter is a somewhat better basis of selection than the first litter, in which the number of pigs is more variable.

The light pigs in a litter usually make less rapid and less economical gains than those that are of average size or heavier.[31] If there are runts in a large litter, it may be best to kill them rather than to waste feed and care upon them. The average weight of pigs at birth is about 2.5 lbs.

1472. Gilts vs. older sows.—It is well known that gilts usually farrow fewer pigs per litter than do older sows. However, they raise a somewhat larger

percentage of the pigs farrowed. In co-operative studies by the United States Department of Agriculture and corn-belt experiment stations, it was found that gilts one year old at farrowing time had an average of 7.92 pigs per litter and raised an average of 5.07 pigs to weaning time.[32] Gilts 1½ years old had 8.49 pigs per litter and raised 5.53. Sows 2 years old farrowed 9.49 pigs per litter and raised 5.99, which was the largest average number raised for any age. However, the average number of pigs farrowed increased up to 3½ years of age, when the average was 9.93 pigs.

The pigs from gilts average slightly smaller in birth weight than those from older sows and also tend to make slightly less rapid gains. In Minnesota studies pigs from gilts averaged about 4 lbs. lighter at weaning time than pigs from older sows, and in Wisconsin studies the difference was 9.4 lbs. at 98 days of age.[33]

Practical hogmen differ widely in their opinions concerning the relative economy of proven older sows and of gilts for pork production. All admit that older sows raise somewhat larger litters of pigs and that their pigs tend to make slightly more rapid gains. However, gilts have certain advantages, as well. Their chief superiority is that they are continuing to grow and appreciate in value for pork while they are producing their pigs. Also, because of their greater smoothness and lighter weight after raising one litter of pigs, they usually sell at a higher price on the market than do older sows.

It was found in Minnesota cost accounting studies that somewhat the best net returns were secured where only about one-half of the sows that farrowed were gilts.[34] Under this system, the sows which produce and raise the best litters are retained as long as they are useful.

In a similar Illinois study it was concluded that there was little choice between gilts and proven older sows, except when the price of pork was sufficiently favorable so that the gain in weight of the gilts could be sold at a decided profit.[35] It should be borne in mind, however, that even young fat sows, after raising their first litters, commonly sell at a considerable discount from the price of fat pigs. Differing from these studies, it was concluded from experiments by the United States Department of Agriculture in Montana and South Dakota that gilts produced pork more economically than did older sows.[36]

The Illinois and Minnesota studies show clearly that when spring-farrowing sows are retained in the breeding herd for further litters, it is unprofitable to raise only one litter a year from them. As many of them as possible should be bred for fall litters in the two-litter method of pork production described later. (**1489**)

The breeder of purebred swine should certainly not rely chiefly on gilts for his breeding herd. Sows which produce especially good litters and which are good milkers and careful mothers should be retained as long as they are useful. Only the offspring from such proven mothers should be chosen for replacements. By careful selection much can be done to build up a herd which is decidedly more profitable than the average. Unless there is some very good reason to expect better returns in the future, one should discard a sow raising a litter of less than 5 pigs, or one which is vicious with her pigs, in spite of being properly fed and cared for. A sow that can save and raise 8 good pigs is an excellent producer and should be retained.

1473. Preparations for farrowing.—Lack of care at farrowing time results in many young pigs being lost through disease or parasites, or from being lain on by the sows. In some seasons 40 per cent of the pigs farrowed in the corn belt die from these causes. These losses can largely be prevented by the right care and management.

At least 3 days before farrowing, each sow should be removed from the herd and placed in a separate farrowing pen, to become accustomed to her surroundings. Previously, the sow should have been cleaned as described later, and the pen should have been cleaned and scrubbed to prevent infecting the young

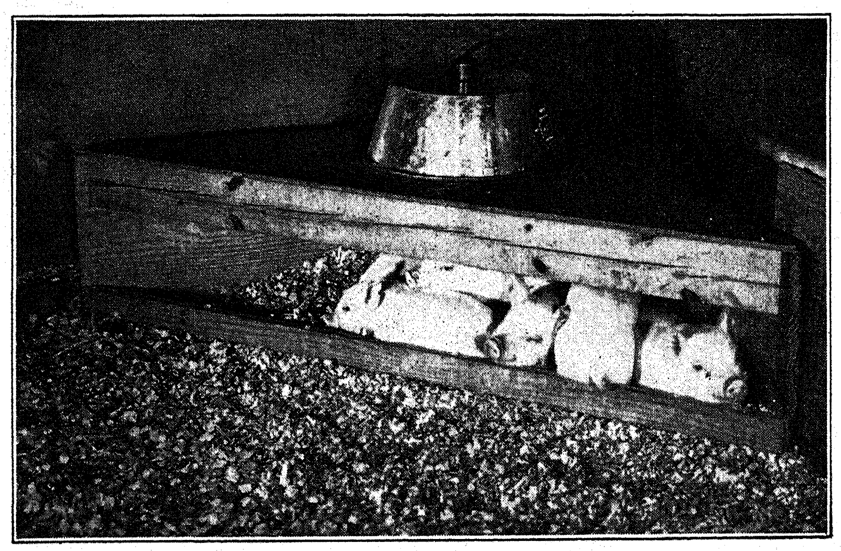
pigs with round worms and other parasites. (1491)

If the breeding dates have not been recorded, the sows should be watched closely as the farrowing season approaches, and each sow should be put in the farrowing quarters as soon as the udder and teats begin to fill. After a sow starts to arrange her nest, she may be expected to farrow within 12 hours. Recording the breeding date is highly important where the litters come before the weather is warm, for otherwise sows will often farrow before it is expected, and their litters may perish from cold or lack of proper care.

A farrowing pen should be dry, well ventilated, free from drafts and well lighted. If possible, it should be exposed for a part of each day to direct sunlight, so it will be warmer.

When a sow farrows during the pasture season, it may be most convenient to have her farrow in a colony house located in a pasture that is free from round worms and other parasites. However, it may then be more difficult to aid her in case she has trouble in farrowing.

Unless electric pig brooders or farrowing crates or stalls are used, each farrowing pen should have guard rails, or fenders, to help prevent the sow from squeezing the pigs against the wall or crushing them when she lies down. These can be made by fastening planks edgewise, like a shelf, 8 to 10 inches above the floor, along both sides of the corner in which the sow makes her bed. If the farrowing pen has a concrete floor, a wood overlay in the nest corner makes the sow's bed warmer and drier.



An Electric Pig Brooder

An electric pig brooder in a corner of the farrowing pen protects the young pigs and keeps them warm in cold weather.

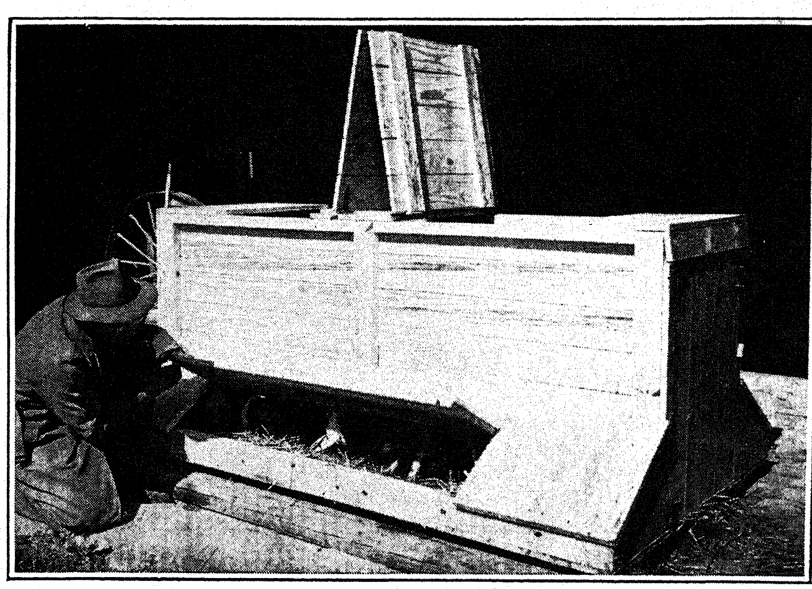
The farrowing place should be sufficiently warm so that a deep nest is not necessary to prevent the new-born pigs being chilled, for they may be crushed in a deep, bird-like nest. Cut straw or hay, shredded stover, chaff, or leaves are best for bedding. Long straw or hay may entangle the pigs.

In cold weather many baby pigs die from chilling, because the mechanism for regulating the body temperature is not well developed until the pigs are at least 2 to 3 days of age.[37] These losses can be largely prevented by some means of keeping the pigs warm during this critical period.

A pig brooder in a corner of the

pen, warmed with an electric light or heat lamp, protects the young pigs and keeps them warm in cold weather. Because of the warmth, the pigs spend much of the time there, where they cannot be lain on or crushed. Where electricity is not available, a similar but unheated hover can be used.

Another method of reducing losses of new-born pigs is the use of farrowing crates or stalls. In these, the sow is so closely confined that she cannot turn



A Portable Farrowing Crate

In a farrowing crate the sow is so closely confined that she cannot turn around. The pigs have access to the spaces on the sides, which serve as brooders.

around. The pigs have access to spaces on the sides, which serve as a brooder and may be heated. Still another way of keeping young pigs warm in cold weather is by suspending a heat lamp over the sow's nest.

Some hogmen use sloping floors in the farrowing pens to prevent the sows from crushing or injuring the pigs. The sow will generally lie with her head up the slope, and away from the side of the pen, where the pigs can be safe.

As soon as the sow is put in the farrowing quarters, her ration should be reduced, for she gets little exercise. The ration should also be made more laxative. A good rule is to feed only one-half to two-thirds as much concentrates as previously, with wheat bran forming one-third of the ration, by weight. Linseed meal is also a helpful addition at this time, and legume hay should be included in the ration, if possible.

1474. Farrowing time.—Few sows need help at farrowing time, but the herdsman should be on hand to render assistance, if necessary. Otherwise, he should not disturb the sow. In large herds it pays to have an experienced man near during the night at this time to inspect the sows every three hours. The farmer with only a few sows will find that a few night trips to the hog house at farrowing time will save many a litter, and prove a wise investment of his time and energy.

In cold weather it is a good plan to dry new-born pigs with a cloth as they arrive. If the pen is not equipped with an electric pig brooder, it is well to put the pigs in a basket or box lined with sacks or other cloth. A jug of hot water

Warm bricks wrapped in cloth can be placed in the center to keep the pigs warm, and the receptacle lightly covered to hold the heat. Separating the pigs thus from the sow as they are farrowed is also wise in the case of heavy, clumsy sows, or those which are very restless. Sows properly handled before farrowing will not usually resent such separation.

The pigs should be kept in this box or basket until farrowing is over, provided the time is not more than 2 or 3 hours. When they are returned to the sow, each pig should be placed at a nipple, and the litter should be watched until their safety is assured. In the case of a very cross sow it may be advisable to keep the pigs away from her for a day or so, returning them to nurse every 2 to 4 hours.

To prevent losses due to navel infection, the navel of each pig should be dipped in tincture of iodine as soon as possible after birth. Experienced hogmen commonly break off the sharp needle teeth of the young pigs with nippers made for this purpose, so the pigs will not lacerate the udder of the sow or wound each other as they tussle among themselves.

Identifying the young pigs by ear-notching them is highly advisable, even in grade herds, so that gilts can be selected for the breeding herd from the best dams.

If brood sows have been kept thrifty by feeding them well-balanced rations and by inducing them to take plenty of exercise, and if constipation is prevented, little trouble will be experienced from sows failing to furnish enough milk for their pigs or from being restless and irritable, which may lead to their eating the young. If a sow has a feverish udder, which is often a result of constipation, a light application of kerosene and lard, well rubbed in, will reduce the congestion and relieve the pain.

Breaking Off the "Wolf" Teeth

Usually experienced breeders break off the "wolf" teeth, or temporary tusks, which pigs have at birth, to prevent lacerating the udder of the sow or wounding the other pigs. (From Wisconsin Station.)

1475. After farrowing.—A sow should have no feed for 12 to 24 hours after farrowing, but should have plenty of water that is not too cold. If she frets

for feed, a handful of wheat bran may be put on top of the water to quiet her.

For the first feeding the sow should get only a double handful of a mixture that is laxative, preferably containing considerable wheat bran. The amount of concentrates should be increased very gradually or the milk flow may be stimulated too soon. This may result in the sow having milk fever or suffering from a caked udder, or in the pigs getting scours. For the second day 2 or 3 lbs. of feed, divided into 2 meals, are sufficient.

During the first few days it is best to use a bulky concentrate mixture containing at least one-third ground oats or wheat bran. Such a mixture may then be changed gradually to the one that is to be fed during the suckling period. After 7 to 10 days a sow should be getting all the feed she will clean up. By this time, the sows and litters should, whenever possible, be put on clean pasture, free from infestation with round worms or other parasites. (1491)

Occasionally, pigs less than a week of age are affected by the "baby-pig disease," or hypoglycemia, in which they become dull and listless and show little desire to nurse. In this condition there is a serious deficiency of glucose in the blood, perhaps caused by semi-starvation, owing to poor milk yield by the sow or to digestive disturbances in the pigs.[38] Pigs not too severely affected may recover if hand-fed every 2 or 3 hours 1 to 2 teaspoonful doses of corn syrup diluted with twice as much warm water.

1476. Milk production of sows.—The gains made by suckling pigs depend largely on the amount of milk their dam produces. It is therefore important to select herd replacements from good milk-producing ancestors.

In various experiments the daily milk production of sows has varied widely, ranging from 4.9 to 11.7 lbs.[39] The daily amount usually reaches the peak from the third to fifth week of lactation. During an 8-week suckling period a good sow should yield 300 to 400 lbs., or even more.

To produce this much milk in this brief period, requires a liberal supply of nutrients. This is shown by the fact that the milk she yields contains several times as much protein, calcium, and phosphorus as there is in the new-born pigs and in the fetal membranes.[40]

Several studies have been made on the composition of sow's milk.[41] It is more concentrated than cow's milk, containing much more protein and fat. (Appendix Table I.) It generally does not differ greatly from cow's milk in vitamin content. As in the case of the milk of other species, the vitamin A content is affected greatly by the vitamin A or carotene content of the ration.

If the feed of sows is very high in percentage of fat, such as fat-rich garbage, the fat percentage of the milk may be increased considerably.[42]

In North Dakota tests it was found that the average interval between the nursings by pigs was 62 minutes, and the longest interval recorded was 175 minutes.[43] There was no marked difference between the intervals in the daytime and at night.

1477. Evening-up litters; orphan pigs.—If a sow has too many pigs to nurse adequately, some should be transferred, if possible, to a small litter of the same age. The method is not successful unless the foster mother has extra teats that are giving a good flow of milk when the transfer is made. The same method can be used in the case of orphan pigs.

The sow should be taken out of the pen when the pigs are added to her litter, and the pigs should be allowed to run together for 10 to 20 minutes before the sow is returned to the pen. Sprinkling a weak solution of stock dip over all the pigs will make it difficult for the sow to distinguish the new arrivals by smell.

Where no sows with litters of about the same age are available for raising orphan pigs, they may usually be raised successfully by hand, if the herdsman has enough patience. It is best to feed the pigs whole sweet cow's milk 5 to 6 times daily until they are 2 to 3 weeks old, when the number of feedings may be reduced to 3 a day. However, in Iowa tests satisfactory results were secured

when pigs were fed only 3 times daily from the beginning.[44]

Some use a nursing bottle at the start, but with patience even the youngest pigs can be taught to drink milk from a shallow dish. The pig's mouth and nose are pushed into the milk, care being taken not to continue the process so long that the pig is strangled. The milk should be about body temperature for the first week or two. To supply the traces of iron and copper necessary to prevent anemia, a few drops of a saturated solution of copperas (ferrous sulfate) should be added to each quart of milk.[40] (**1403**)

A maximum of one quart of milk a day is enough per pig, if they are supplied with a suitable concentrate mixture as soon as they can be taught to eat solid food. Care should be taken to supply fresh water at all times. If whole milk is not available, fresh skimmilk or even buttermilk can be substituted, according to the Iowa tests. It is not necessary to add cream or sugar to whole milk for orphan pigs, though this is sometimes recommended.

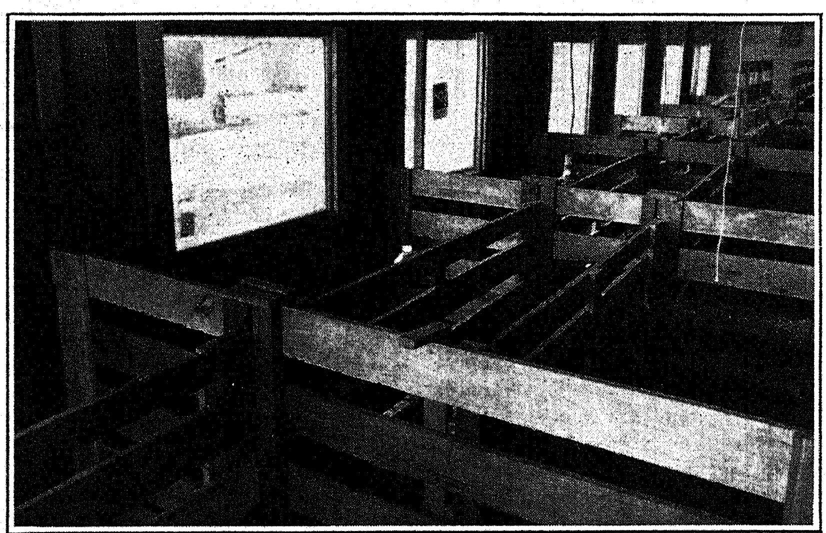
If young pigs do not get the colostrum milk from a sow, it is much more difficult to rear them, as the colostrum protects them against various infections. (**270**) When the orphan cannot get colostrum from a sow, it should be fed colostrum from a cow for a couple of days, if possible.

A commercial milk replacer can also be used for raising orphan pigs, instead of cow's milk. (**1483**)

III. Raising the Pigs

1478. Feeding sows that are suckling litters.—During the suckling period, brood sows must be fed much more liberally than during pregnancy, because of the additional nutrients needed for the production of a good flow of milk. Not only should they receive more grain to furnish the necessary total digestible nutrients and energy, but also the supply of protein, calcium, phosphorus, and vitamins must be considerably greater, since milk is rich in these nutrients.

In general, the nutrient requirements of brood sows suckling litters are similar to those of dairy cows for milk production. The requirements of brood sows of various weights are stated in the feeding standards in Appendix Table III.



A Hogbarn with Removable Farrowing Stalls

At farrowing time, the sow is confined to a farrowing stall, just as in a farrowing crate.

It is essential that sows with litters be fed enough concentrates to produce a good milk flow. Otherwise, the young pigs will not get a good start. It should be remembered that at no other time do pigs make as economical gains as when suckling their dams. When on full feed, a 400-lb. sow nursing a litter will need 8 to 12 lbs. of concentrates a day, the exact amount depending on her condition and on the number of pigs in the litter.

The concentrates may consist chiefly of corn and other grains, but sufficient protein of good quality must be fed to balance the ration properly. (1385) Such supplements as tankage, meat scrap, fish meal, dairy by-products, or soybean oil meal are especially important when the sows are not on pasture. Protein supplements that supply poorer-quality protein, such as linseed meal, cottonseed meal, or wheat middlings, may be used in combination with those first mentioned.

As stated in the preceding chapter, rations for gilts nursing litters should have not less than 15 per cent of total protein, and rations for mature sows at least 14 per cent. (1388) Experiments have proved that even when sows have been fed good rations during pregnancy, rations deficient in protein when they are nursing their litters produce poor results.[45] The gains of the pigs are much less, there is a greater death loss, and the sows lose more weight.

When the sows and pigs cannot be put on pasture by the time the pigs are 2 weeks old but are confined to pens and paved lots, anemia of the suckling pigs should be prevented by using one of the methods described previously. (1403) For sows and pigs not on pasture, it is also wise to supply a suitable mineral mixture in addition to common salt, unless one is sure there is no lack of calcium or phosphorus in the ration.

If the sows are not on pasture, 5 to 10 per cent of ground or chopped alfalfa or other legume hay should be included in the concentrate mixture to furnish carotene, vitamin D, and other vitamins, or choice legume hay should be fed in a rack.

Corn may be fed as ear corn or shelled corn (preferably soaked if it is hard and dry), or it may be ground and mixed with the other concentrates. The smaller cereals should always be ground for sows, if possible.

Because of the large amounts of nutrients needed in milk production, sows that are good milk producers may lose much weight while nursing their litters, even when they are fed liberally. This means that the amount of nutrients they can assimilate from their feed is insufficient to furnish the nutrients in the milk, and therefore they draw temporarily on the store in their bodies.

Several example rations for brood sows suckling litters are given in Appendix Table VII. These will serve as guides in making up a ration that will be most economical under one's local conditions.

1479. Methods of feeding brood sows and litters.—Brood sows with litters may be hand-fed 2 or 3 times a day, or they may be self-fed. In the self-feeding method both sows and pigs have access to a suitable concentrate mixture at all times in a self-feeder.

If a sufficient amount of a bulky feed, such as alfalfa meal, wheat bran, or oats, is included in the self-fed mixture, the sows may be put on the self-feeder when the pigs are only 2 to 3 days old.[40] The mixture should gradually be made more concentrated as the sows and pigs need more nutrients.

Self-feeding not only saves labor, but it also ensures a plentiful supply of feed at all times. It is especially desirable when several sows are in the same lot, as there is no quarreling at the feed trough, and each pig can get all it wants. To save feed, sows with less than 5 or 6 pigs had best be sorted out and fed a limited ration.

Self-feeding sows and litters proved preferable to hand-feeding in experiments by the United States Department of Agriculture and also in a Kansas test.[46] In the former trials, self-fed sows gained an average of 12.8 lbs. and their pigs an average of 20.4 lbs. during 41 days, while hand-fed sows lost an average of

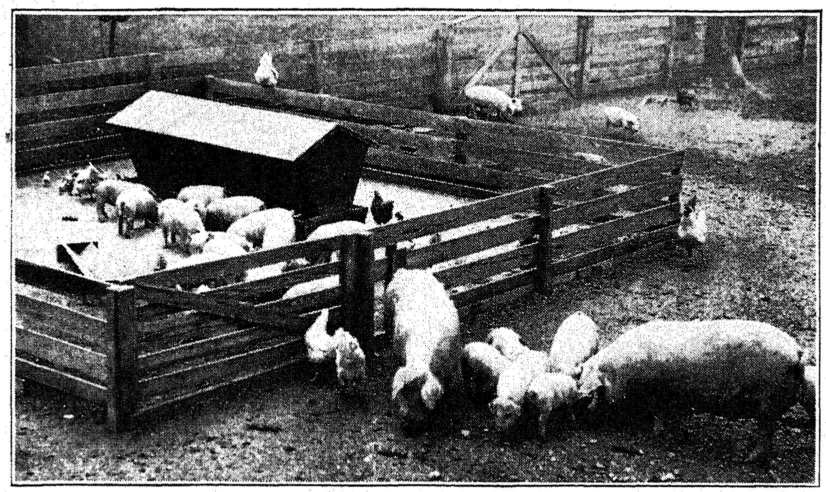
11.6 lbs. and their pigs gained an average of 17.0 lbs. during 44 days. The self-fed pigs also continued to make more rapid gains after weaning. For 100 lbs. gain of sows and litters combined, only 441 lbs. of feed were required by the self-fed lot, in comparison with 603 lbs. for the hand-fed lot. Also, when the sows were bred before their pigs were weaned, 81 per cent of the self-fed sows settled at the first service and only 47 per cent of those that were hand-fed. It has been shown previously that the self-feeding method is not adapted to feeding pregnant sows, unless the proper amount of very bulky feed is included in the mixture, and the proportion of such feed is changed from time to time so as to keep the sows in proper condition. (1466)

When sows suckling litters are self-fed a well-balanced ration, there is little advantage in supplying separate feed for the pigs in a creep.

Good pasture, free from infestation with parasites, is especially beneficial to young pigs, because of the protein, minerals, and vitamins it provides, and also because pigs get an abundance of exercise when on pasture.

If the pigs show a tendency to become too fat the first few weeks, the dam's ration should be reduced gradually, so she will give a little less milk. Scours should be avoided by keeping the quarters dry and clean and the troughs sanitary. Overfeeding the sows or letting the pigs run out in a cold rain are other frequent causes of this trouble.

Boar pigs not to be kept for the breeding herd should be castrated when 3 to 6 weeks old. This should be done on a clear, cool day, and the pigs should be kept in dry, clean quarters afterwards. Before the operation the pigs should receive only a light feed.



YOUNG PIGS FEEDING IN A CREEP

When the sows are hand-fed instead of being self-fed, additional feed should be supplied the suckling pigs by means of a creep.

1480. Creep-feeding; pig starters.—When sows suckling litters are hand-fed, additional feed should be supplied the pigs by means of a creep, as soon as they are 1 to 2 weeks old. A creep is an enclosure in a corner of the paddock or pen, with openings of such size that the pigs can run in and out, while the sows are excluded. Here the pigs are provided palatable concentrates, in either a small trough or a small self-feeder.

For use in a pen of a central hog house, where space is limited, a creep-feeding trough can be used. Such a

trough has a cover extending out far enough so the sow cannot get at the feed, while the pigs can reach it beneath the cover.

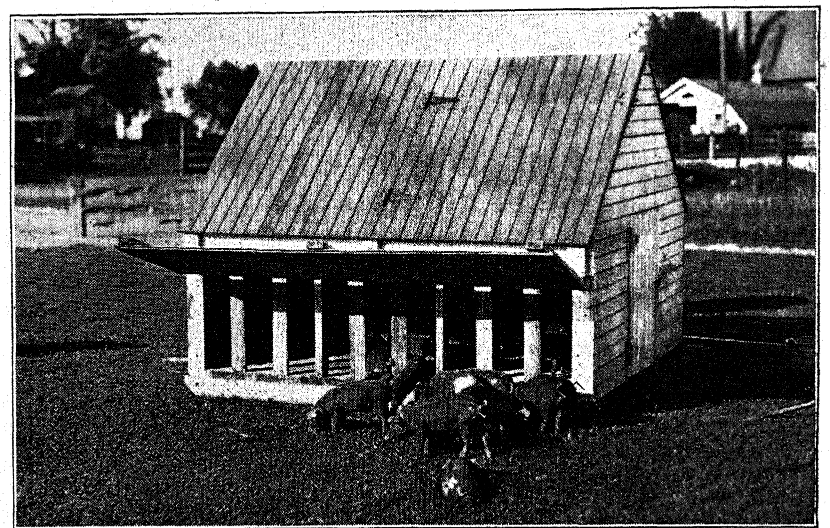
Creep-feeds are often called "pig starters." Suitable mixtures for creep-feeding are given in Appendix Table VII.

The purpose of creep-feeding is to supply the young pigs with as great an amount of nutrients as possible during this period of very efficient growth. Therefore the creep-feed should be highly palatable to them. Several experiments have been conducted to compare the results from various creep-feeds, or pig starters.[47]

These have shown that young pigs do not like a very fine, dusty mixture, and they prefer shelled or cracked corn to that which is ground fine. One good method of creep-feeding is to supply separately shelled corn and an efficient protein supplemental mixture, free-choice. Good ingredients in such a supplement are soybean oil meal, meat scrap, fish meal, and dried dairy by-products.

For pigs not on pasture a pig starter should contain 2.5 to 5 per cent of high-quality alfalfa meal and an antibiotic supplement. There may be no advantage from including an antibiotic supplement in a pig starter for pigs running with their dams on good pasture.

Oat groats, or hulled oats, are very palatable to young pigs and are an excellent ingredient in pig starters. Adding 10 per cent of cane sugar or cane molasses to a complete starter usually increases the palatability somewhat. In some tests pelleted starters have given slightly better results than starters in meal form, but not in other trials.



A COLONY HOUSE ARRANGED AS A CREEP

Here the young pigs get additional feed and are also provided with shelter and shade.

Where skimmilk or buttermilk is available, little or no other protein supplements are needed. Shelled corn and sufficient of one of these dairy by-products make an excellent combination.

1481. Weaning time.—When only one litter of pigs is raised a year, the pigs may run with their dam 10 to 12 weeks, or the sow may be allowed to wean the pigs herself. However, when 2 litters are raised yearly the pigs must be weaned not later than the age of 7 to 8 weeks, as sows do not commonly come in heat until after their pigs are weaned.

When the litters are to be weaned at this age, the amount of concentrates fed the sows should be reduced for a few

days before weaning, in order to check the milk flow. If the sows and litters have been self-fed on pasture, it is best to shut the sows away from the self-feeder by means of a creep 3 to 4 days before weaning. For this short period the sows will get enough nourishment from the pasture. If a sow's udder becomes unduly distended with milk after she is taken away from her pigs, it may be necessary to return her to the pigs for a few minutes every second day until she dries off.

It is especially important that clean pasture, free from contamination with round worms and other parasites, be provided for the pigs after weaning. If there is much difference in the ages of the various litters, it is best to group them according to size, subdividing a pasture, if necessary. Pigs will do best if there are not over about 20 in a group, as there is then less crowding in the colony house on cold nights. However, a much greater number may be successfully kept in a large pasture, if self-feeders and colony houses are well distributed, instead of all being located at one point.

Since the pigs no longer get their mother's milk, the ration after weaning should contain a larger proportion of protein-rich feeds than before. For weanling pigs in dry lot, the ration should have at least 18 per cent protein. (**1388**)

Several rations for pigs after weaning and also at later ages are given in Appendix Table VII. These will serve as convenient guides in selecting suitable combinations under the conditions in any particular locality.

Rations for weanling pigs should, if possible, include a protein supplement of animal origin, such as meat scrap, tankage, fish meal, or dairy by-products. A liberal amount of skimmilk or buttermilk, fed with grain, is unexcelled at this time.

Where no fluid skimmilk or buttermilk is available, weanling pigs in dry lot will usually make slightly more rapid gains when a little dried skimmilk, dried buttermilk, or liver meal is added to such a ration as corn and a trio mixture. (**894, 913**) Owing to the usual high prices of these feeds, such an addition may not be economical for pigs being raised for market, while it may be desirable in raising purebred breeding stock.

As is shown in the preceding chapter, the gains of young pigs are generally appreciably increased and the feed efficiency slightly improved when an antibiotic-vitamin B_{12} supplement is added to a good ration. (**1422**) The needs of pigs for the various vitamins and the use of supplements supplying B-complex vitamins and other vitamins have been previously discussed in detail. (**1406–1420**)

1482. Weaning pigs early.—During recent years there has been considerable interest in weaning pigs before the usual age of 7 to 8 weeks. Under some conditions early weaning has definite advantages, but it also has certain limitations and disadvantages.

Weaning at 3 weeks of age is generally successful with thrifty, vigorous pigs, if they are fed a special dry ration, and particularly if the care and management are much better than usual.[48]

Weaning at an earlier age is not practical under most conditions.[49] If pigs are weaned at only a few days of age, they must be fed an expensive milk replacer in liquid form, and even then the results may be inferior to later weaning.

Feeding the reconstituted milk replacer requires additional bother and labor. Also, very strict cleanliness of troughs and equipment is essential. Most milk replacers contain considerable dried skimmilk or other dried milk by-products, and must be completely reinforced with vitamin and mineral supplements, as well as with an antibiotic-vitamin B_{12} feed supplement.

Weaning at 3 weeks of age aids in securing 2 litters a year, especially with sows that farrow late in the spring. With unusually careful management 5 litters may even be obtained in 2 years. When spring litters are weaned at 3 weeks, the sows to be sold can be marketed earlier in the season, when the price is often better than later.

Pigs that are to be weaned at 3 weeks should be creep-fed, while they

are with the sows, the same dry mixture that will be used later. This may consist mostly of an efficient pig starter, but at least one-quarter of the mixture should be a more expensive, completely reinforced milk replacer.

In Minnesota trials pigs weaned at 3 weeks made nearly as rapid gains as those which nursed the sows 8 weeks.[50] Up to 8 weeks of age, the feed cost per pound of gain, including the feed eaten both by the pigs and by the sows, was slightly higher for the early-weaned pigs.

In an Illinois experiment pigs weaned at 20 days of age gained 0.32 lb. a day to 7 weeks, in comparison with 0.41 lb. for pigs which were not weaned until that old.[51] The feed cost per pig, including the feed of pigs and sows, was higher for the pigs weaned early.

1483. Milk replacers, or prestarters.—Many experiments have been carried on during recent years in endeavors to develop milk replacers, or prestarters, which would successfully replace sow's milk for early-weaned pigs.[52] A milk replacer must be fed in reconstituted warm liquid form, or as a gruel, at least during the first few days.

The successful milk replacers commonly contain a considerable proportion of dried skimmilk or other dried dairy by-products, and also such cheaper feeds as ground oat groats (without the hulls), ground corn or other grain, dehydrated alfalfa meal, soybean oil meal, meat scrap, fish meal, and other protein supplements. Often the mixture contains sugar (glucose, lactose, or cane sugar) or cane molasses, and a small percentage of added fat. The milk replacer should be well fortified with complete mineral and vitamin supplements and with an effective antibiotic.

Several of the larger formula feed manufacturers make such milk replacers. Because of the complexity of the formulas, milk replacers are not adapted to mixing on the farm.

The early weaning of pigs has been discussed in the preceding article. While the removal of pigs from the sows at only a few days of age is sometimes recommended, this is apt to result in poorer growth and greater death losses than weaning them when 3 weeks old or more.

The formulas for certain milk replacers which have given good results in experiment station trials are stated in Appendix Table VII.

1484. Pig hatcheries.—A few farmers have specialized in the large-scale production and sale of weaned pigs, usually about 8 weeks old.[53] Such enterprises are often called "pig hatcheries."

With excellent equipment and most expert care and management, the number of pigs raised per litter may be considerably greater than on most farms, thus reducing the cost per weaned pig. Usually early weaning is practiced, so that at least 2 litters a year can be produced per sow.

The financial returns from pig hatcheries have varied widely. In some cases such enterprises have been given up because of poor results due to serious disease outbreaks, or to lack of the skillful management necessary in such an undertaking.

1485. Growing and fattening pigs.—To produce rapid and cheap gains, growing and fattening pigs must receive well-balanced rations that provide a sufficient amount of protein and also protein of good quality. Likewise, care must be taken that their mineral and vitamin needs are fully met, which have been discussed in the previous chapter. Several example rations for pigs in dry lot and also for those on pasture are given in Appendix Table VII. The values of the various grains and other concentrates are discussed in the chapters of Part III.

Whenever possible, good pasture should be provided for growing pigs, on account of the advantages that have been emphasized previously. When pigs cannot be on pasture, legume hay should be included in their ration as insurance against a deficiency of vitamins. (**1417**) For pigs not on pasture it is important to use an efficient protein supplement, such as discussed in the preceding chapter. (**1418–1420**)

Whether to fatten spring pigs for market early in the fall by self-feeding

them concentrates on pasture, or to force them to consume more pasture by restricting their concentrate allowance, will depend on the relative prices of grain and pasture, and the prices for pork at the various times in the fall and winter, as has been shown previously. (1432)

Detailed information has been given in the preceding chapter on the effects on the carcass and on the feed efficiency of feeding a limited ration to fattening pigs. (1429–1432)

Pigs should always be provided with an abundance of fresh water in a trough or an automatic waterer. If self-feeders and automatic waterers are used, it should be borne in mind that even with these labor-saving devices one cannot expect success if he does not give the proper attention to his pigs. One should see daily that the feeders and waterers are working properly and should clean them out when necessary.

If the pigs are on first-class pasture and are fed such supplements as skimmilk, tankage, or fish meal, there is probably little or no advantage in feeding any other mineral supplement than salt. However, for pigs not on good pasture, feeding a simple mineral mixture, such as has been recommended before, may be advisable, even when protein supplements of animal origin are used.

1486. Artificial light.—Since artificial light at night increases the egg production of hens in winter, it was suggested that it might increase the feed consumption and the gains of self-fed fattening pigs. However, in an Illinois trial and a Minnesota test, light turned on automatically for 2 periods at night did not significantly affect feed consumption or gains.[54]

1487. Raising breeding stock.—Pigs selected for the breeding herd, both sows and boars, should be fed so they will develop good size and strong bone, but should not be allowed to become as fat as pigs that are being finished for market. If the spring pigs are fed a limited allowance of concentrates on good pasture and receive a well-balanced ration, it may not be necessary to separate the gilts to be retained for breeding from the other pigs until full-feeding is started in the fall.

On the other hand, if the pigs intended for the market are being fattened as they grow by self-feeding or by hand-feeding them all they will eat, it is best to separate the breeding stock soon after weaning, so they may be fed a ration suited to their needs. However, if the pigs are being fed a well-balanced ration and are of a growthy type, the gilts may be safely kept with the market pigs until they reach a weight of 125 to 150 lbs. After this, the amount of concentrates should be limited, so the gilts will not get too fat.

Special care should be taken that the ration for pigs being raised for breeding stock contains sufficient protein and protein of good quality, and that there is an abundant supply of calcium, phosphorus, and vitamins. Such pigs should be on good pasture during just as much of the year as is possible. This is the best insurance against any lack of vitamins. When pasture is not available, 10 to 15 per cent of legume hay should be included in the ration.

Breeding swine may be raised with success on grain (even corn) as the chief concentrate, if the grain is properly supplemented and if the amount is limited so that the pigs do not get too fat. However, most breeders prefer concentrate mixtures containing at least 25 to 30 per cent of such bulky feeds as ground oats, wheat bran, or standard middlings. If possible, some protein-rich feed of animal origin should be included in the ration, such as meat scrap, tankage, fish meal or dairy by-products. This is especially important if the pigs are not on first-class pasture.

If plenty of skimmilk or buttermilk is fed, an excellent combination is one-half to two-thirds corn, barley, or grain sorghum, with the remainder oats or standard middlings and with pasture or legume hay in addition.

Sows and boars of the larger breeds should reach a weight of 350 lbs. or more at one year of age, if properly fed and managed.

In a Minnesota trial fall-farrowed

gilts were fed a limited ration in winter and also on pasture the next summer, in comparison with full-fed gilts.[55] When they farrowed in the fall, the limited-fed gilts weighed an average of only 304 lbs. and had eaten 959 lbs. of feed per head, in addition to pasture. The full-fed gilts averaged 429 lbs. and had consumed 1,632 lbs. of feed. The liberally-fed gilts farrowed an average of 1.2 more pigs per litter, and their pigs weighed 4.2 lbs. more per head at weaning.

In Washington and Wisconsin experiments gilts raised on limited rations reached puberty slightly earlier than did those fed liberally.[56]

1488. Age to breed gilts.—Gilts are generally bred so that they will farrow when about a year of age. However, purebred gilts that are intended for a show herd are often not bred until they are somewhat older, so that they will reach a larger size.

It was proved many years ago by extensive experiments at the Missouri Station that breeding well-fed sows in successive generations to farrow at less than a year of age was not injurious and did not reduce their mature weights.[57] Sows that were bred early were only slightly smaller at 20 months than later-bred sows, and they finally became fully as large.

When early and frequent breeding was combined with scanty feeding, the sows did not reach normal size. This checking of growth was due to the heavy drain on the sows when they were fed scantily during lactation.

The pigs in the first litters of young sows are slightly smaller at birth than those from older sows, and they also make a trifle less rapid gains. In commercial pork production this is much more than offset by the additional cost of maintaining a later-bred sow for a longer period before she produces her first litter.

1489. Two litters vs. one litter a year.—Whether it will be more profitable to follow the two-litter-a-year method of pork production or to use the one-litter system will depend on the local conditions, especially on the winter climate and on the shelter and feed that can be provided.

When the one-litter system is followed, the pigs are nearly all farrowed in the spring and few or no sows are bred for fall pigs. Commonly, gilts are used chiefly or entirely in this system, and in the summer after they have weaned their first litters they are fattened for market. Only gilts are used, because it does not pay to maintain an older sow an entire year to raise only one litter.

Under the two-litter system; the sows are bred to farrow sufficiently early in the spring so that the fall litters can get a good start on pasture before cold weather comes on. Sows usually come in heat a few days after their litters are weaned, but not during the suckling period. Since the fall litters should be farrowed by September, this means that the spring litters must come not later than March. Raising two litters a year should therefore not be attempted in the North unless these early pigs can be given proper shelter and care.

Even when an endeavor is made to raise two litters a year from all the sows possible, there will usually be more spring litters than fall litters. Often, some of the spring-farrowing sows will not become pregnant from the first service, and then it may be too late in the season to breed them again for fall litters. Under this system, however, it is easily possible to raise an average of three litters every two years.

Where the climate is mild, the two-litter system is usually decidedly more profitable than the one-litter method. The fall litters should prove as satisfactory as the spring pigs, for they can be furnished pasture until late in the fall and in the southern states also in winter. Even in the northern states, excellent results are secured from fall pigs when they are properly fed and cared for.

In the corn belt the two-litter system has several advantages, as well as certain disadvantages. The chief advantages are: (1) A maximum use is made of capital invested in equipment; (2) the breeding herd may be improved more readily by

retaining sows that produce large litters of pigs that prove efficient in the feed lot; (3) there is a better distribution of labor; (4) under the two-litter system pigs can be marketed at the two times of the year when the prices are usually highest—in early fall and in spring; and (5) there is a better distribution of farm income.

These advantages are offset to some extent by the fact that the death losses are usually higher in pigs farrowed early in the spring, as is necessary in the two-litter system, than they are in litters farrowed later when the weather is more favorable.

In cost studies on Illinois, Indiana, and Minnesota farms and in South Dakota experiments during 5 years, the two-litter system was more profitable than the one-litter method.[58] The possibilities for increased profits with the two-litter system under careful management are well shown by the results of the South Dakota studies. On the average, the net return per sow was $110.70, in comparison with only $42.14 per sow in the one-litter method.

1490. Fall pigs.—Even in the northern states pigs which are farrowed early in the fall and which get a good start on pasture make satisfactory and economical gains. However, under poor conditions fall pigs are apt to be a disappointment where the winters are cold.

In Minnesota trials fall pigs that were well housed and fed efficient rations in dry lot from shortly after weaning required 404 lbs. of feed per 100 lbs. gain; spring pigs fed in dry lot, 402 lbs.; and spring pigs on pasture, 390 lbs. not including the pasture eaten.[59] Because of a higher price per hundredweight, the net return was considerably greater from the fall pigs.

In South Dakota experiments over a period of 5 years, fall pigs required an average of 446 lbs. of feed, including that eaten by the sows, per 100 lbs. of pork produced.[60] For spring pigs the requirement was 413 lbs. of concentrates, in addition to pasture. The net return per 100 lbs. of pork produced was higher for spring pigs.

In the South where pasture can be provided during all or most of the winter and where the weather is hot in summer, fall pigs may make more rapid and more economical gains than spring pigs. This was the case in Tennessee experiments with pigs which were either full-fed or fed limited rations on pasture.[61] Fall pigs also made more rapid gains than did spring pigs in Texas trials, but the fall pigs needed about 9 per cent more feed per 100 lbs. gain.[62]

Where the winters are cold, fall pigs should be farrowed early enough to be well started before the cold comes on. It is important that clean pasture be provided for sows with fall litters, as this aids greatly in keeping the pigs thrifty. Where the climate is suitable, the pigs should also be on good pasture at weaning time and for as long afterward as possible. This will enable them to build up a store of vitamins in their bodies to help overcome any shortage during the winter.

To keep fall pigs thrifty after the pasture season and to secure rapid and economical gains, they must receive efficient rations. The importance has been emphasized in the previous chapter of feeding pigs in dry lot rations that provide: (1) Plenty of protein; (2) protein of good quality; (3) ample minerals; and (4) an abundant supply of vitamins. As shown previously, it is especially important to include well-cured legume hay as vitamin insurance in rations for growing pigs not on pasture.

Efficient supplemental mixtures for growing and fattening pigs in dry lot have been discussed in detail in the preceding chapter (**1418–1420**) An antibiotic-vitamin B_{12} feed supplement increases the gains and helps keep the pigs thrifty. (**1422**)

If plenty of skimmilk or buttermilk is available, the ration for fall pigs may consist of only grain and the dairy by-product, with legume hay in addition. For pigs under 75 lbs. in weight it is advisable to add to a ration of corn, skimmilk, and legume hay a small amount of some other protein supplement, as young pigs full-fed on corn will often not drink

enough milk to balance the ration completely.

Suitable, well-ventilated dry quarters must be provided for fall pigs, where they can be kept comfortable during cold, wet weather. They should be supplied with sufficient bedding, and this should be replaced when it becomes damp.

1491. Sanitation and disease prevention.—Sanitation is fully as important as proper feeding in pork production. If hogs are raised on the same ground year after year with little or no regard for proper sanitation, there will be heavy losses from round worms and other parasites and also from filth-borne diseases. As a result of these conditions, many pigs will die before they get to market, and others will become unprofitable. On the other hand, under an efficient system of swine sanitation, including the use of clean, uncontaminated pasture for the young pigs, such losses can be largely prevented.

The common round worm of swine is one of the chief causes of death or lack of thrift among young pigs, and also is one of the most injurious parasites in older swine. Under usual conditions, probably one-third of the hogs of breeding age are infected to a greater or less extent with these parasites.

It is difficult to control round worms, because the eggs, which are voided in the feces from infected swine, are resistant to freezing, thawing, or drying and also are not killed by most chemical disinfectants. However, they are soon killed by exposure to sunlight in a dry place.

The "McLean County System of Swine Sanitation," developed by the United States Department of Agriculture, not only controls round worms but also largely prevents trouble from other internal parasites and from filth-borne diseases, such as necrotic enteritis.[63] The effectiveness of this system is based upon the fact that when the round worm eggs are first passed out of the body of a hog in the feces they are not infectious. In a few weeks or longer, tiny worms develop in the eggs. If then swallowed by swine, the eggs will hatch and the worms will infect the swine.

The eggs are of microscopic size and are present in the manure of infected hogs or in soil contaminated by such manure. One full-grown female worm may produce as many as 80,000,000 eggs. The eggs may remain alive in the soil for a year or more.

The incubated eggs which are swallowed by pigs hatch in the small intestine. The young worms, which are too small to be seen by the naked eye, then penetrate the wall of the small intestine and are carried in the blood through the liver to the heart and lungs. In the lungs the small worms migrate through the blood vessels and invade the lung tissues. From the air spaces in the lungs, the worms are coughed up by the pigs into the throat and swallowed. The worms, which are now only one-fifteenth to one-twentieth inch in length, grow to adult size in the intestines in a period of 2 to 3 months.

The greatest injury to young pigs occurs when the worms are in the lungs. In case of a heavy invasion, many abcesses are produced, the pigs become unthrifty, and many die from pneumonia. Common indications of infestation are coughing and difficult breathing, sometimes known as "thumps." In the later intestinal stages, the worms may also be decidedly injurious if many are present. This is especially the case when they invade the gall bladder and the ducts of the liver.

The following are the essentials of the McLean County system:

1. The farrowing pens should be cleaned thoroughly, all dirt, dust, and bedding being removed. Then the floors and the walls for 2 feet from the floor should be scrubbed with boiling water, to each 30 gallons of which 1 lb. of lye has been added. After the pen has been scrubbed it is wise to spray it with a reliable disinfectant. The lye does not kill the round worm eggs, but is necessary to loosen the dirt, and thus remove the eggs. The hot water kills some of the eggs and the lye and the disinfectant kill disease germs.

2. Before the sow is put in the farrowing pen, all dirt and litter should be

carefully brushed from her sides and legs, and her udder, legs, and feet washed with warm water and soap. A single small chunk of dirt remaining on the sow may contain enough round worm eggs to stunt a pig that swallows it.

3. Until they are taken to pasture, the sow and pigs must be confined to the farrowing pen, or to the pen and a paved adjacent outside lot which has been similarly scrubbed. The sow and litter should

SCRUBBING THE PEN

In the McLean County system of sanitation, the farrowing pen is scrubbed with a hot lye solution.

be hauled (not driven) to a pasture where no pigs have been kept for at least a year, and which preferably has been cultivated since it was last used by hogs. If the pigs are driven over contaminated ground, they may pick up enough worm eggs on the way to lessen greatly the benefits from the system.

4. The pigs should be kept on clean pasture until they are at least 4 months old, after which time they are much less susceptible to injury from round worms or other parasites, or to infection with necrotic enteritis or other filth-borne diseases.

Where the soil is sandy and well-drained it may not be necessary to wash the sows before farrowing. Also, when sows farrow during the pasture season, they can be housed in portable colony houses located in the clean pasture where they are to remain after farrowing. The floor of the colony house should, of course, be cleaned and scrubbed as advised in the case of the farrowing pen.

The benefits from following an efficient system of swine sanitation are shown by studies which have been made of the cost of pork production on various farms. For example, on Illinois farms where the McLean County system was followed, 55 lbs. less feed was required per 100 lbs. gain than on farms where no sanitation system was used, and the total cost per 100 lbs. of hogs marketed was 19 per cent less.[64]

Even when good sanitation is followed, some pigs may become infected with round worms. In all such cases a reliable worm expellant should be used. Care should also be taken to eradicate lice by greasing, spraying, or dipping swine with crude oil or waste crank case oil. Mange should be eradicated by treatment with crude oil, or kerosene mixed with lard or cottonseed oil, or lime sulfur solution.

Where hog cholera is common, the only safe plan is to immunize all swine by vaccination.

1492. Shipment to market; shrinkage.—To reduce the shrinkage in weight of hogs during shipment to market certain precautions should be taken. Indiana studies show that where hogs are trucked not over about 100 miles to market and can be fed after arrival, it is best to give them a normal feed the previous evening, but not to feed them at the farm the morning of shipment.[65] They should be hauled to market early in the morning and be given a corn and water fill at the market.

Hogs shipped a longer distance should be fed grain before shipment.[66] However, they should be given only a rather light feed, especially in hot weather, so they will be less apt to overheat.

Because they are accustomed to unground corn, hogs that are finished on shelled corn or ear corn are apt to fill better on shelled corn and water at the market than those which have had ground feed. It is probably not advantageous to confine pigs that have been on pasture to a dry lot for a few days

before shipping them. This may reduce the shrinkage between home weights and market weights, but some shrinkage will have already occurred in the change from pasture to dry lot. If hogs have been fed slop, it may be wise to use dry feed for a few days before shipment.

In driving or loading the hogs, care must be taken not to hurry or excite them, and they should not be beaten or bruised. Crippled hogs sell at a severe discount, and bruises also lower the selling price, as they injure the carcass.

When hogs are shipped by rail, they should reach the shipping station in plenty of time for them to become rested and cooled before they are loaded. The car should be thoroughly cleaned before loading and should be bedded with sand, as this furnishes better footing than straw or than no bedding at all.[67] In hot weather hogs should be sprayed with a hose before loading and also when possible at stopping points in transit. If the weather is very hot, suspending from the roof of the car sacks containing large cakes of ice, helps prevent overheating. In extreme winter weather it is a good plan to protect the hogs from cold winds by nailing a few strips of building paper on the inside of the car.

Indiana experiments show that the shrinkage is increased when a car is loaded too full.[68] However, if there are not enough hogs to fill it comfortably when they are lying down, the shrinkage will also be greater, because of jostling around.

The average percentage of shrinkage for hogs shipped by rail for various distances in the Indiana studies ranged from 1.35 per cent for those shipped less than 62 miles, to 1.89 per cent for those shipped 263 miles or more. The percentage of shrinkage was somewhat greater for heavy hogs than for lighter ones, probably because heavy hogs cannot handle themselves so well and they tire more easily. Also, they may not fill so well at the market.

In studies by the United States Department of Agriculture, the shrinkage was determined between the purchase weights of hogs bought by packers at shipping points in the country and the shrunk weights after shipment to the packing plants.[69] Hogs in transit 7 to 12 hours shrank an average of 5.3 per cent in summer and 4.1 per cent in winter. Those in transit 55 to 60 hours shrank 8.9 per cent in summer and 7.9 per cent in winter.

Most of the shrinkage is due to excretion of feces and urine, but part is due to actual tissue shrinkage. It was estimated that the tissue shrinkage was less than 1 per cent of the live weight for hogs in transit 7 to 12 hours, and about 3 per cent for hogs in transit 55 to 60 hours.

It was found in the Indiana studies that the shrinkage increased as the temperature rose, except that the shrinkage was also higher when the temperature was less than 18 to 27° F. The shrinkage was lowest in late fall and in winter when the hogs had been fattened on dry feeds. It was greatest in spring when pasture was lush, and in early fall when a large proportion of the hogs had probably been finished on new corn. The percentage shrinkage of hogs is considerably greater in mixed carloads of hogs and other stock than it is in straight carloads of hogs.

In Illinois studies there was no marked difference in percentage of shrinkage when hogs were shipped the same distance by rail and by truck, though there was a tendency for the shrinkage to be slightly higher for truck shipment.[70] The losses by death and crippling were only about one-half as great in Indiana studies for hogs trucked (usually less than 75 miles), as they were for hogs shipped by rail (generally 75 to 175 miles).[71] Part of this difference was, of course, due to the greater distance of the rail shipments.

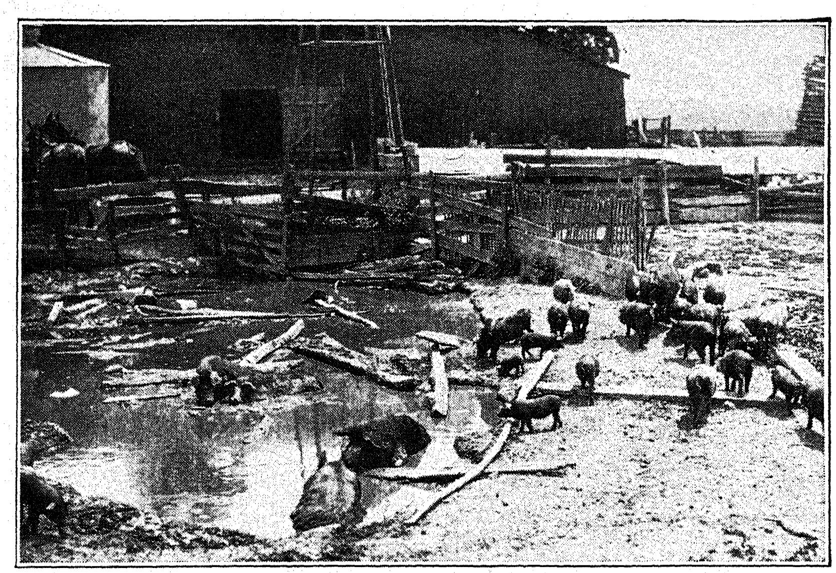
1493. Cost of pork production.— The cost of producing pork will vary widely from year to year and also during the same year in various sections, depending chiefly upon the prices of feed. The cost of feed, including pasture, will commonly form 75 to 85 per cent of the total cost of producing 100 lbs. of marketable hogs. Man labor, the next largest

cost, is usually less than 10 per cent of the total cost. To the cost of feed and man labor must be added the expenses for horse or tractor labor, equipment and shelter, interest, veterinary services, and miscellaneous items, including death losses.

In extensive cost accounting studies on farms in various corn belt states a total of 428 to 505 lbs. of concentrates has been required, on the average, in producing each 100 lbs. of marketable live hogs.[72] This includes the feed eaten by the breeding herd, but does not include hay or pasture consumed. Skimmilk fed on some of the farms has been reduced to an air-dry basis.

In Illinois studies there were required per 100 lbs. of marketable live hogs: 400 lbs. corn, 73 lbs. other grain, 7.7 lbs. miscellaneous concentrates, 2.0 lbs. hay, and 1.5 lbs. minerals, or a total of 484 lbs., including hay.[73] In studies in southeastern Minnesota, a dairy district where skimmilk was fed on many of the farms, the average requirement per 100 lbs. of marketable hogs was: 316 lbs. corn, 124 lbs. other grain, 14 lbs. other concentrates, and 459 lbs. skimmilk.[2]

In the Illinois studies the total cost of producing each 100 lbs. of marketable hogs was equal to 11.1 times the average farm price of corn per bushel. This relationship, called the corn-hog ratio, varies considerably in various years, depending on the price of corn compared with the level of other costs. For example, in studies by the United States Department of Agriculture when corn was very cheap, the cost of producing 100 lbs. of hogs was 15.2 times the farm price of corn per bushel.[74]



UNDER THESE CONDITIONS PROFITS CANNOT BE EXPECTED

Pigs which have no pasture and are in filthy, unsanitary quarters make expensive gains. Many become runts or die because of disease or infection with worms.

On the Illinois farms the sows in the breeding herds consumed an average of 2,075 lbs. of feed per head in addition to pasture during the year. On many of the farms gilts were used solely or chiefly for breeding, and these were sold as soon as they could be fattened after weaning their first litters.

In these studies approximately 30 per cent of the total cost of producing pork was for the maintenance of the

breeding herd and 70 per cent for the growing and fattening pigs.

1494. Reducing the cost of pork production.—These cost studies and also similar other investigations show clearly the ways in which the cost of pork production may be reduced and the net returns increased on the average farm.[75]

One of the most important factors is the average number of pigs raised per litter. When the number weaned per litter is small, the pigs will start into the fattening period with a cost handicap that cannot be overcome by the most efficient feeding and care. In the Minnesota studies, the average net return over cost of feed, per 100 lbs. of hogs marketed, was $1.70 on farms where an average of 7 pigs or more were weaned per litter, and only 80 cents on farms where the average number weaned was 5 or less.[2]

Large litters at weaning time can be secured only by a combination of efficient breeding and selection of breeding stock, the feeding of excellent rations to brood sows and young pigs, and proper housing and care of the sows, including the use of guard rails or pig brooders to protect the young pigs.

Other factors of prime importance in increasing the net returns from pork production, which have been emphasized previously in this and the preceding chapter, are: Providing good pasture throughout the growing season; efficient control of internal parasites and certain diseases by sanitation; the feeding of economical well-balanced rations to growing and fattening pigs; and planning the swine enterprise so that the hogs are ready for market at the times of the year when prices are best.

THRIFTY PIGS RAISED UNDER SANITARY CONDITIONS

These thrifty pigs on clean alfalfa pasture are a striking contrast to those in unsanitary quarters.

The importance of abundant good pasture for swine is shown by the records on 200 Illinois farms.[76] On the one-third of the farms where the most pasture was provided only 417 lbs. of concentrates were required per 100 lbs. of hogs marketed. On the farms having the least pasture, the requirement was 462 lbs. of concentrates.

The best returns are, of course, secured by highly efficient farmers who excel in all the ways of reducing the cost of

production. For example, in the Minnesota studies farmers who excelled in all the factors necessary for low cost pork production, received a net income over cost of feed of $2.79 on each 100 lbs. of hogs marketed.[2] Those who excelled in only half the important factors received a net income of only $1.49 per 100 lbs. of hogs marketed, and those who were below average in all factors did not get enough income from their hogs to pay for the cost of feed.

In a recent cost study of pork production on Iowa farms, only 58 per cent as much feed was required to produce 100 lbs. of live hogs on the one-third of the farms that were most efficient as was needed on the least efficient one-third.[77]

QUESTIONS

1. Discuss the importance of pasture for swine.
2. What are the best pasture crops for swine in your region?
3. What do the Minnesota cost studies show concerning the value of pasture?
4. What results have been secured in experiments in which growing and fattening pigs on pasture have been compared with those in dry lot?
5. What factors should be considered in selecting brood sows and boars?
6. State 6 essentials in the feed and care of brood sows.
7. What grains are most commonly fed to brood sows in your region?
8. Discuss the feeding of brood sows on grain alone during pregnancy.
9. Why is it important to feed legume hay to brood sows not on pasture?
10. Discuss the use of legume hay as the only protein supplement for sows.
11. Which protein-rich feeds are satisfactory as the only protein supplement for brood sows? Which protein supplements should be fed in combination with more efficient supplements?
12. Discuss the use of corn for brood sows. How do barley and oats compare with corn in value for sows?
13. Under what conditions should other mineral supplements than salt be fed to brood sows?
14. How would you regulate the amount of grain for pregnant sows? Is it generally advisable to self-feed pregnant brood sows?
15. Discuss the importance of exercise for brood sows.
16. How should brood sows be fed during the summer?
17. Why is it advisable to "flush" sows shortly before breeding time?
18. State the most important points concerning the feed and care of the boar.
19. What are the advantages and disadvantages of gilts in comparison with older sows?
20. State briefly how you would feed and care for a sow: (a) Previous to farrowing; (b) at farrowing time; (c) immediately after farrowing.
21. About how much milk does a good sow produce during a lactation period?
22. How are litters "evened up?"
23. Discuss the feeding of sows that are suckling litters.
24. What sort of a feed should be used for creep-feeding suckling pigs?
25. Discuss the early weaning of pigs.
26. What feeds and supplements should a milk replacer contain?
27. Are there any pig hatcheries in your state? How successful have they been?
28. Discuss the feeding and care of pigs and sows at weaning time.
29. In what respect should the feeding of pigs which are being raised for breeding stock differ from that of pigs which are being fattened for market?
30. What have experiments shown concerning the effects of breeding gilts at an early age?
31. State the advantages and disadvantages of the two-litter-a-year method of pork production in comparison with the one-litter method.
32. How do fall pigs compare with spring pigs in rate and economy of gains, when properly fed and cared for?
33. What are the essentials for success with fall pigs?
34. Discuss the importance of sanitation and disease prevention in pork production.
35. Describe the McLean County system of round-worm control, stating the facts in the life history of the round worm upon which the effectiveness of the system depends.
36. What precautions would you take to reduce the shrinkage when hogs are shipped to market?
37. Discuss the main factors in the cost of pork production.
38. What are the ways in which the cost of

pork production may be reduced on the average farm?

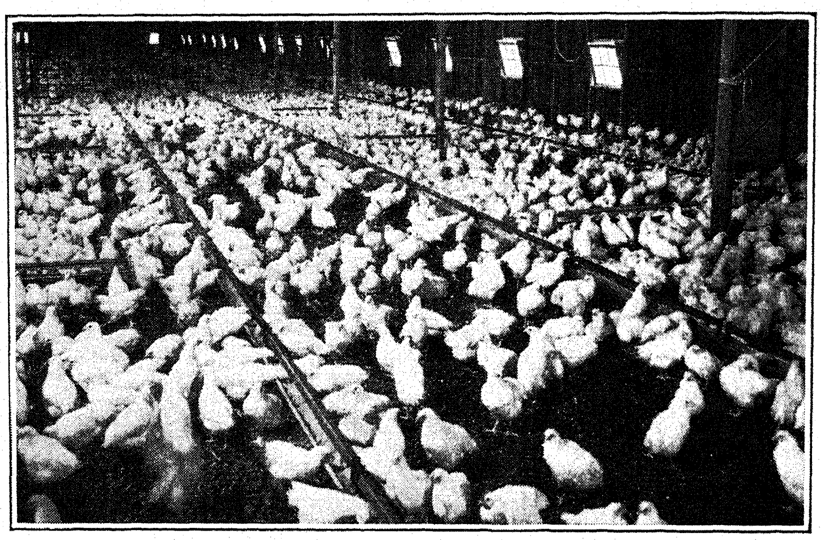
CHAPTER XXXVI

GENERAL PROBLEMS IN POULTRY PRODUCTION

I. Nutrient Requirements of Poultry

1495. Modern poultry production revolutionized by nutrition discoveries.— The discoveries in poultry nutrition during recent years have made possible revolutions in poultry production. Before these discoveries were made, attempts to raise chickens in confinement were often unsuccessful. Also, the egg production of hens was generally unsatisfactory unless fresh green feeds were supplied and unless the hens could get out into sunlight during a considerable part of the year.

Through hundreds of careful experiments most of the nutrient requirements of poultry have now been definitely determined. Their needs are known for protein and amino acids; for minerals, including trace minerals; and for vitamins, including certain unidentified vitamins, or factors. Numerous investigations have also shown that the rate of gain and the feed efficiency of growing poultry can be increased by a suitable antibiotic feed supplement. High-energy rations have been developed, especially for broiler production, which considerably reduce the amount of feed required per pound gain in weight. Much progress has also been made in the control of diseases.



A Large-scale Modern Broiler Plant

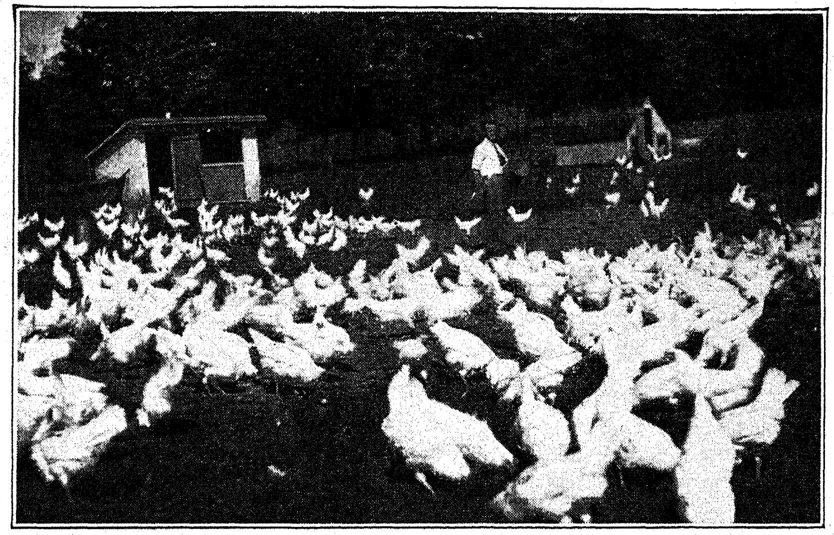
The discoveries in poultry nutrition during recent years have made possible intensive, large-scale poultry production.

As a result of these experiments thrifty chicks can now be raised in confinement and at any time of the year. Also, laying hens can be kept healthy and productive without fresh green feed and without exposure to sunlight. These discoveries have made possible the development of successful intensive meth-

ods of poultry production, in which little or no range or pasture may be used. Sometimes hens are even confined during most of their lives in small individual compartments, or batteries. Although such conditions are far different from those natural for fowls, the hens thrive to a surprising degree, because their nutritive requirements are known and can be fully met.

required per pound of broiler produced, with a range from 2.8 lbs. to 5.4 lbs.[4]

When broilers are fed, with expert management, the best possible high-energy rations, supplemented amply with minerals and vitamins and with an effective antibiotic feed supplement, the gains can now be surprisingly efficient. For example, in a Maryland test recently completed with 7,860 birds of both sexes,



A FARM FLOCK OF CHICKENS

Although modern, scientific methods have made possible intensive, large-scale poultry production, the majority of the chickens in the United States are kept in farm flocks, under more natural conditions. This flock has excellent pasture in summer. (From New York State College of Agriculture, Cornell University.)

the broilers weighed an average of 2.83 lbs. at 8 weeks of age and had required only 2.21 lbs. of feed per pound of weight.[5]

The great changes that have resulted from these recent developments are shown by the following: Only 10 years ago, the average annual egg production per hen in the United States was about 110 eggs.[1] Now, in commercial flocks the annual egg production per 100 hens is estimated at over 18,000 eggs, and above 20,000 eggs in some states.[2]

In cost accounting studies of broiler production only a few years ago, it was found that 4.2 to 4.8 lbs. of feed were required per pound of broiler marketed.[3] In a study for 1951–1952 of the results of 80 New York broiler producers, an average of only 3.7 lbs. of feed were

Large-scale intensive methods of poultry production are of great importance in certain sections of the United States, but the majority of the chickens in the country are kept in farm flocks, under more natural conditions. Here they can get no small part of their feed by foraging during the growing season. Also, they utilize considerable feed that might otherwise be wasted, such as garbage and surplus vegetables.

Of the total number of poultry in

the United States, over 90 per cent are chickens. Because of the great importance of chickens compared with other poultry, the following discussions deal chiefly with them. Brief summaries concerning the production of turkeys, ducks, and geese are given in the next chapter.

1496. Digestion in poultry.—The digestive systems of poultry are much different from those of the larger farm animals.[6] Poultry have no teeth with which to chew their food, the teeth and lips being replaced by the horny beak or bill. Such soft feeds as vegetables, green herbage, or meat can be torn into pieces by the beak, but hard substances like grain are swallowed whole. Since no chewing is done in the mouth, abundant saliva is not needed, and the salivary glands are not well developed.

From the mouth the food is forced down the gullet into the crop, a pouch-like enlargement of the gullet just before it enters the body cavity. The food is stored temporarily in the crop and softened somewhat. From the crop it passes on in small quantities, as it can be accommodated for grinding in the gizzard.

Such hard feeds as whole grain may remain in the crop 12 hours or more. In New York studies 30 to 40 per cent or more of the feed generally remained in the crop 12 hours after it had been eaten.[7] Within 24 hours practically all of it had passed out of the crop.

There is little or no secretion of enzymes in the crop. However, a little digestion may be produced by enzymes contained in the feed, by ptyalin of the saliva, and by bacterial action.

From the crop the food passes through the second part of the gullet into the glandular stomach (called the proventriculus), where the gastric juice is secreted. The food does not remain here any appreciable time, but passes on, mixed with the acid gastric juice, into the gizzard, or muscular stomach (called the ventriculus).

The gizzard is a powerful, muscular grinding apparatus, with a tough horny lining. In it the food is finely ground with the aid of grit or small pebbles. Though grit is not necessary for the grinding action of the gizzard, it enables chickens to make more efficient use of whole grains and coarse, fibrous feeds. (**1514**)

From the gizzard the partly-digested food passes into the small intestine, in which the digestive processes are similar to those in other farm animals. Most of the gastric digestion takes place in the first part of the small intestine. Farther along, the food is acted on by the bile, the pancreatic juice, and the intestinal juice.

The large intestine in poultry has but small capacity and is of minor importance in digestion. It consists of a short rectum and two ceca, or blind guts, at the juncture of the small intestine and the rectum.

In poultry the urine and the feces are not voided separately, but both are excreted through a common chamber, called the cloaca. Most of the water in the urine is reabsorbed in the cloaca, and the urine is voided as a whitish paste with the feces. The nitrogenous waste is excreted chiefly in the form of uric acid and urates, instead of urea, as with mammals.

1497. Digestibility of feeds by poultry.—For feeds low in fiber, such as corn, wheat, or the grain sorghums, there is no great difference in the digestibility by poultry and by cattle or sheep. On the other hand, the digestibility by poultry of feeds high in fiber is low. This is because they have little ability to digest fiber, except that in some green forages and in roots.

Since the urine is not voided separately by poultry, digestion trials cannot be conducted with them by the same methods that are used with the larger farm animals. To determine the approximate digestibility of feeds by poultry, methods have sometimes been used to separate the feces from the urine, or to estimate the amount of nitrogen in the urine.

1498. Feeding standards; nutrient allowances.—Feeding standards based upon digestible nutrients are not commonly used in poultry feeding. This is because there is very little information concerning the actual amounts of digest-

ible nutrients furnished to poultry by various feeds.

The standards for poultry are generally stated in terms of total protein and of other required nutrients. Also, because of the small size of poultry, the standards are usually stated in terms of the amounts of the various nutrients required per pound of feed, instead of the allowances per head daily. For these reasons, feeding standards for poultry are not included in the feeding standards presented in Appendix Table III.

The standards used generally in this country are those prepared by a special committee of the National Research Council in a report entitled, *"Recommended Nutrient Allowances for Poultry."* [8] These standards for chickens, which have been recently revised, are given in detail in the following table. The standards for turkeys are given in Chapter XXXVII.

Nutrient requirements of chickens [1]

	Starting chickens 0–8 weeks	Growing chickens 8–18 weeks	Laying hens	Breeding hens
Total protein, per cent	20	16	15	15
Vitamins				
Vitamin A activity (U.S.P. Units) [2]	1200	1200	2000	2000
Vitamin D_3 (International Chick Units)	90	90	225	225
Thiamine, mg.	0.8	?	?	?
Riboflavin, mg.	1.3	0.8	1.0	1.7
Pantothenic acid, mg.	4.2	4.2	2.1	4.2
Niacin, mg.	12	?	?	?
Pyridoxine, mg.	1.3	?	1.3	1.3
Biotin, mg.	0.04	?	?	?
Choline, mg. [3]	600	?	?	?
Folacin, mg.	0.25	?	0.11	0.16
Minerals				
Calcium, per cent	1.0	1.0	2.25 [4]	2.25 [4]
Phosphorus, per cent [5]	0.6	0.6	0.6	0.6
Salt, per cent [6]	0.25–0.50	0.25–0.50	0.5	0.5
Potassium, per cent	0.2	0.16	?	?
Manganese, mg.	25	?	?	15
Iodine, mg.	0.5	0.2	0.2	0.5
Magnesium, mg.	220	?	?	?

1 These figures are estimates of requirements and include no margins of safety.
2 May be vitamin A or carotene.
3 May be partially replaced by betaine.
4 This amount of calcium need not be incorporated in the mixed feed, inasmuch as calcium supplements fed free-choice are considered as part of the ration.
5 At least 0.45 per cent of the total feed of starting chickens should be inorganic phosphorus. All of the phosphorus of non-plant feed ingredients is considered to be inorganic. Approximately 30 per cent of the phosphorus of plant products is non-phytin phosphorus and may be considered as part of the inorganic phosphorus required. A portion of the phosphorus requirement of growing chickens and laying and breeding hens must also be supplied in inorganic form. For birds in these categories the requirement for inorganic phosphorus is lower and not so well defined as for starting chickens.
6 This represents salt or sodium chloride added as such or in marine or fermentation products of high sodium chloride content. In the table published by the committee, the added salt requirement is given as 0.5 per cent for all classes of chickens. Because of the results secured in recent experiments with chicks, the author has given in this table a range of from 0.25 to 0.50 per cent of added salt in rations for starting chicks and for growing chickens. (1510)

It is important to note that these revised standards are estimates of minimum requirements and do not include any margins of safety, such as there are in the feeding standards for other animals, given in Appendix Table III. To provide for variations in the composition of feeds and differences in the requirements of individual birds, the amounts

recommended of certain nutrients in the earlier standards were considerably above the estimated minimum needs.

For example, the following margins of safety were provided in the earlier standards: Vitamin A for hens, over 60 per cent; vitamin D, 50 per cent; B-complex vitamins, 20 per cent.

In using the preceding table to formulate practical rations, it is therefore important to see that the amounts of nutrients provided are sufficiently above these minimum requirements to be safe under all conditions.

The requirements of chickens for the various nutrients are considered in detail in the articles which follow. Information concerning the desirable proportions of various types of ingredients in poultry rations is given in the example rations presented in Appendix Table VII. These rations may readily be modified to meet the conditions in various regions.

1499. Percentages of protein.—The protein requirements of poultry are commonly stated in terms of the percentages of total protein (not digestible protein) which are needed in rations for good results when the protein is of satisfactory quality.

In the standards of the committee of the National Research Council, which have been given in the preceding table, not less than 20 per cent total protein is advised in a ration for chicks up to 8 weeks of age, and 16 per cent from 8 to 18 weeks of age. For laying hens, including breeders, the minimum recommended is 15 per cent.

Chickens fed high-energy rations, which are discussed later, need a slightly higher percentage of protein than do those fed rations containing more fiber. **(1533)** This is because a little less weight of feed is usually consumed on a high-energy ration. For the birds to secure the proper amount of protein per day, the percentage of protein must be slightly higher.

Formula feed manufacturers consequently give attention to the proportion, or ratio, between the Calories of net energy, or productive energy, and the percentage of protein in high-energy mashes.[9] **(1531)**

Numerous experiments have been conducted to compare various levels of protein in rations for growing chickens.[10] These experiments have shown that good gains are made on rations containing the percentages of protein stated in the table. However, the rate of gain may be slightly more rapid, especially for chicks of the heavier breeds, if the ration has at least 21 per cent of protein for the first 6 to 8 weeks, and then at least 17 per cent.

In a recent New York experiment with Single Comb White Leghorn pullet layers fed a high-energy ration, 15 per cent of total protein was sufficient for a strain of birds that reached a mature average weight of 5 lbs.[11] Pullets of a smaller strain, which averaged about 4 lbs. in weight at maturity, needed between 15 and 16.5 per cent of protein in the ration.

When hens are fed mash and scratch grain and consume about equal weights of each, the mash should have not less than 20 to 21 per cent of protein. This will provide about 15 per cent of protein in the entire ration.

Poultry on protein-rich pasture, such as alfalfa or Ladino clover, need considerably less protein in the concentrates than do hens not on pasture. In experiments in Scotland, rations having only 11 to 12 per cent protein were adequate for hens on good pasture.[12]

1500. Quality of protein.—In poultry rations it is fully as important to have protein of good quality as it is to have a sufficient amount of protein. **(107–129)** Rations in which the protein comes entirely from grain and grain by-products produce poor results, because of poor quality of protein, even if there are ample supplies of minerals and vitamins.

Fish meal, meat scrap, tankage, and dairy by-products have a high value as protein supplements in poultry rations. **(114, 121, 845, 905, 920)**

Fish meal and also skimmilk and other dairy by-products are very efficient in correcting the deficiencies in the proteins of the grains and the grain by-products. Meat scrap and tankage are

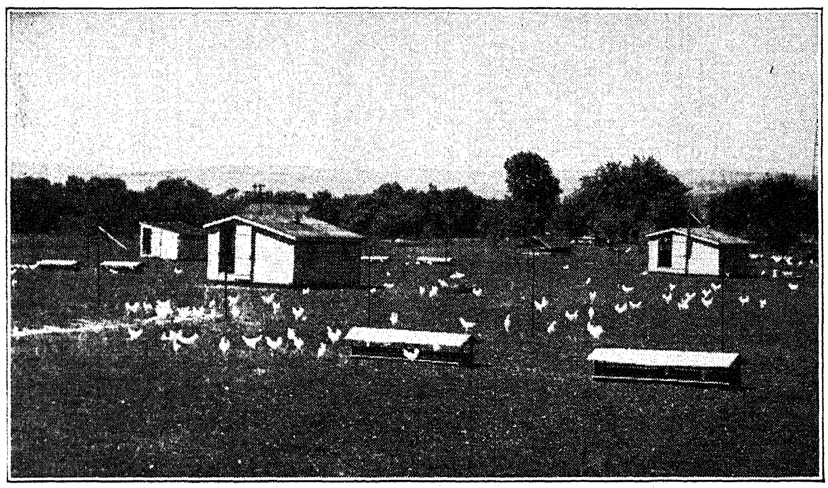
also effective protein supplements for the grains, except that in a ration consisting almost entirely of corn and one of these supplements there may be a slight deficiency of tryptophan, as is pointed out later. (**1503**)

Excellent results are secured when only these feeds of animal origin are used to balance grains and grain by-products in poultry rations, with whatever mineral or vitamin supplements are needed in addition. However, it is generally cheaper and more economical to use much smaller amounts of these animal-protein supplements than would be required to balance a ration fully, and to supply a large part of the needed protein by protein supplements of plant origin.

Part of the high value for poultry of the protein supplements of animal origin is due to their richness in calcium and phosphorus and also in their content of vitamins. Therefore, when plant-protein supplements are used as the only or the chief protein supplements in poultry rations, care must be taken to add whatever mineral and vitamin supplements may be needed.

The value and use for poultry of the many different protein supplements are discussed in detail in the chapters of Part II. It is there emphasized that soybean oil meal which has been properly cooked in the manufacturing process ranks next to the protein supplements of animal origin for poultry. (**806**)

If the ration is properly supplemented with calcium, phosphorus, and riboflavin, soybean oil meal gives excellent results when it replaces the major part of the animal-protein supplements needed to balance rations for chicks, growing pullets, or laying hens.



Good Pasture Helps Meet the Nutrient Requirements

Poultry on good pasture, such as this, have an abundance of most vitamins. Also, the pasture forage helps to meet the protein and mineral requirements. (From New York State College of Agriculture, Cornell University.)

If care is taken to supply proper amounts of minerals and vitamins, reasonably good egg production and growth of chicks can be obtained when soybean oil meal replaces all of the animal-protein supplements. However, for the best results, a certain minimum amount of feeds of animal origin should be included in the ration. In the case of poultry that are confined, there is a greater benefit from including in the ration such supplements as meat scrap, fish meal, or dairy byproducts, than there is for poultry which are on good pasture. This is due both to the quality of protein in good pasture

forage and to the worms and insects they secure on pasture.

Peanut oil meal probably ranks next to soybean oil meal as a substitute for animal-protein supplements. (**841**) Corn gluten meal is a satisfactory substitute for one-half of the meat scrap in poultry rations, but should not be used as the chief protein supplement, as the protein is not of high quality. (**716**) Similarly, corn distillers dried grains should be used only in combination with supplements which provide protein of good quality. (**954**)

1501. Minimum proportions of animal-protein supplements.—Numerous experiments have been conducted to determine the minimum proportions of animal-protein supplements that are needed in poultry rations for optimum results.[13]

The example rations in Appendix Table VII indicate the percentages of feeds of animal origin commonly recommended in poultry mashes. For the best results, starting mashes for chicks should generally have at least 5 to 7 per cent of animal-protein supplements. Complete mashes for growing chickens and laying hens should contain not less than 3 to 4 per cent of animal-protein supplements; mashes to be fed with grain to growing chickens and laying hens, 5 to 7 per cent; and breeding mashes to be fed with grain to hens producing hatching eggs, 7 to 10 per cent.[14]

It should be remembered that these are the minimum percentages of animal-protein supplements recommended for optimum results. When there is a plentiful supply of feeds of animal origin and the prices are not unduly high, somewhat larger proportions of these feeds are desirable in poultry rations.

1502. Amino acid requirements.—The approximate percentage of each of the essential amino acids required in rations for chicks has been determined by adding definite amounts of the particular pure amino acid to a diet low in this amino acid. Similar data have been secured for a few amino acids in experiments with laying hens. The requirements for chicks and for layers are shown in the following table. The information concerning the amino acid requirements of turkey poults is summarized in Chapter XXXVII.

The data in this table are mainly the requirements stated in the report of the committee of the National Research

Essential amino acid requirements	Starting chicks Per cent of ration	Laying hens Per cent of ration
Arginine	1.7	...
Glycine [1]	1.0	...
Histidine	0.15	...
Isoleucine	0.6	0.5
Leucine	1.4	1.0
Lysine	1.0	0.5
Methionine	0.7	0.53
or		
Methionine,[2] plus	0.33	0.28
Cystine	0.35	0.25
Phenylalanine	1.6	...
or		
Phenylalanine,[3] plus	0.9	...
Tyrosine	0.7	...
Threonine	0.6	...
Tryptophan	0.15	0.15
Valine	0.8	..

1 The chick can synthesize glycine, but not at a rate sufficient for maximum growth. Glycine can be replaced by serine and partially by arginine.

2 Cystine will replace part of the methionine, as long as the ration contains not less than the percentages of methionine shown.

3 Tyrosine will replace part of the phenylalanine, as long as the ration contains not less than 0.9 per cent phenylalanine.

Council, which has been mentioned previously.[8] Where more recent experiments have provided further information, changes have been made by the author in the requirements for certain amino acids.[15]

It should be borne in mind that this table shows the percentages of the amino acids needed in the entire ration. When chickens are fed both a mash and grain separately, the mash must supply sufficient of the essential amino acids to correct the deficiencies in the protein of the grain, and provide the proper amounts in the entire ration.

The numerous investigations on the amino acid requirements of chicks have shown that the only amino acids which may be deficient in practical, well-balanced rations are methionine, tryptophan and lysine. Since hens apparently need smaller percentages of the essential amino acids than do chicks, it is not likely that there will be a deficiency, even of these amino acids, in rations that are otherwise satisfactory for layers.[16]

1503. Correcting amino acid deficiencies.—Appendix Tables VIIIa and VIIIb give the approximate percentages in important feeds of the essential amino acids, and also of cystine, which can partially replace methionine. Table VIIIa states the percentages of the amino acids in the various feeds, while Table VIIIb states the percentages of the different amino acids there are *in the protein* of the particular feed.

Since feeds differ very widely in protein content, the latter table best shows whether the protein of a given feed is a good source of any amino acid, or whether it is low in it.

By the use of Table VIIIa, a formula feed manufacturer can determine whether or not a particular mash formula will provide sufficient percentages of the essential amino acids. It must be remembered that data concerning the minimum requirements of the different amino acids are still limited, and that various lots of the same kind of feed apparently differ considerably in content of the important amino acids.

If a certain mash formula seems to be deficient in lysine, tryptophan, or methionine, then the formula should be modified to correct the lack. This can be done by including in the mash a sufficient amount of a feed that is rich in the particular amino acid which is in short supply.

As has been pointed out previously, methionine is the only pure essential amino acid which is at present available at a price that makes its use feasible in practical rations. In addition to pure methionine, certain related compounds, called methionine analogues, are available commercially. These can be used instead of methionine, because they can be converted into methionine within the body.

The following examples show how an amino deficiency can be corrected by the use of a feed rich in the particular amino acid. The protein in all of the cereal grains is low in lysine. Corn, milo, and barley are especially deficient. To correct this lack, a protein supplement rich in lysine must be included in the ration.

Peanut oil meal or degossypolized cottonseed meal does not provide sufficient lysine to correct the deficiency, if either of these feeds is used as the only or the chief protein supplement to corn or other grain.[17] The lack can be remedied by using soybean oil meal, meat scrap, tankage, fish meal, dried skimmilk, or brewers' dried yeast to furnish enough of the protein in the ration.

A combination of corn supplemented entirely by meat scrap or tankage may be a little deficient in tryptophan.[18] Soybean oil meal, fish meal, degossypolized cottonseed meal, dried skimmilk, sesame oil meal, and distillers dried solubles all have more than twice as much tryptophan per pound of protein as does meat scrap or tankage. (Appendix Table VIIIb.) Therefore, the tryptophan lack can be corrected by including sufficient of one or more of these feeds in the mash. Alfalfa meal and wheat standard middlings also have a good content of tryptophan. However, because of their fiber content and bulk, only a small percentage of these feeds can be included in a chick mash.

There is commonly no lack of leucine in poultry rations. However, it has recently been reported that when all the grain in a ration for laying hens is wheat or barley, there may be a lack of this amino acid.[19] Corn and milo have more leucine than do wheat and barley. Corn gluten meal, sorghum gluten meal, fish meal, meat scrap, and tankage are rich in it, and cottonseed meal, distillers solubles, and dried skimmilk are good sources.

The manner in which the deficiencies in the protein in each of two feeds can be corrected when they are combined properly, is shown by the data in Appendix Table VIIIb for corn gluten meal and for soybean oil meal. Corn gluten meal protein is low in lysine, but it has considerably more methionine than does soybean oil meal. On the other hand, soybean oil meal protein has a good content of lysine and tryptophan, but is rather low in methionine. When these two feeds are combined, the amino acid deficiencies of each are corrected.

1504. Methionine supplementation.—Rations for chicks in which soybean oil meal, peanut oil meal, or degossypolized cottonseed meal is used as the only or the chief protein supplement may not supply quite enough methionine for the most efficient gains. This is of particular importance in large-scale broiler production.

Only a few feeds supply more methionine than do these protein supplements. Fish meal commonly has more than twice as much, and sesame oil meal and well-hulled sunflower-seed oil meal are good sources of methionine. There is as yet much less information concerning the content in feeds of cystine, which can partially replace methionine.

Because of the few natural feeds that have a liberal amount of methionine, many experiments have been conducted recently, usually with broilers, to determine the effects of adding pure methionine to the ration. While the results of the trials have differed decidedly, in the majority of the tests conducted by the experiment stations, the amount of feed required per pound of gain has been appreciably reduced by the methionine supplement.[20] In many trials this has occurred even when the rate of gain has not been increased.

Whether there will be sufficient improvement in feed efficiency to cover the cost of the added methionine will depend chiefly on the amount in the ration of fish meal or other good sources of the amino acid.

Usually only 0.5 to 1.0 lb. of methionine is added per ton of mash. A methionine analogue should be used as directed by the manufacturer. More than the recommended amount of methionine supplement may be definitely detrimental.

1505. Fat.—Experiments in which chicks have been fed rations in which all the fat has been removed have shown that they may require very small traces of the highly unsaturated fatty acids discussed in Chapter V.[21] (133) On the other hand, if hens need these fatty acids, they can apparently synthesize the necessary amounts in their bodies.[22]

Any practical poultry ration furnishes sufficient fat and enough of these unsaturated fatty acids for good results. Therefore, in feeding standards for poultry, it is not necessary to state any minimum requirement of fat.

In several trials the effects have been studied of feeding rations in which most of the fat has been extracted experimentally. Chicks made normal growth in Indiana experiments on a ration containing only 1 per cent fat, and in New Jersey studies the growth was nearly as rapid on a ration having only 0.1 per cent fat as on a normal ration.[23] In a Louisiana trial the growth of chicks was somewhat slower on a ration containing practically no fat, but the effect was overcome during later growth.[24] On a low-fat ration the body fat is harder than normal, since practically none of it comes from the feeds and nearly all is made from the carbohydrates. (276)

In New Jersey experiments with laying hens, reducing the fat content of the ration to 1.6 per cent had no unfavorable effect on egg production, fertility, hatchability of eggs, or mortality.[25] However, when a ration was fed which had prac-

tically no fat (containing only 0.07 per cent fat) the utilization of carotene was greatly decreased. The absorption of vitamin A was not reduced, but much less of the vitamin was stored in the liver than on a normal ration. These effects are probably due to the fact that carotene and vitamin A are both soluble in fat.

In an Arizona experiment, egg production was nearly normal on a ration having only 0.8 per cent fat.[26] However, in a Louisiana trial a ration having practically no fat decreased egg production and lowered hatchability.[27]

1506. Addition of fat to rations.—The addition of by-product animal fat to livestock rations has been previously discussed in general. (134) Because of the surplus of such greases and tallows during recent years, the prices of these fats have fallen to levels that have made their addition to formula feeds practicable. Several experiments have therefore been conducted to find the effects of adding such fats to poultry mashes.

The fat addition increases the energy value of a ration, and consequently the birds generally eat a somewhat smaller weight of feed. It is therefore important to have in the mash enough protein, vitamins, and minerals to offset this lower feed consumption. Also, a fat should be used to which an effective antioxidant has been added, to prevent rancidity and vitamin destruction. Hydrogenated fat with a very high melting point is not utilized well by poultry.

In the experiments with broilers and other chicks, adding up to 8 or perhaps 10 per cent of by-product grease or tallow to a good mash has increased the feed efficiency in most cases.[28] Adding a greater percentage may be less desirable. Also, mash having as much as 12 per cent of added fat may tend to cake in cold weather. The effect of the fat addition on rate of gain has differed, and in some cases the gain has not been increased.

In these experiments the added fat has generally had a somewhat higher value per pound than would be expected from its energy value. This is commonly estimated at 2.25 times the energy value of a pound of starch.

The addition of fat to the ration during the finishing period for broilers may be especially advantageous, because it tends to increase the fleshing and the fat content of the meat.

In a New York trial with laying hens, the addition of 2.5 or 5 per cent tallow to a high-energy ration did not significantly increase egg production in fall, spring, or summer.[29] On the other hand, the fat addition consistently increased egg yield in winter.

The addition of fat appreciably decreased the weight of feed required per dozen eggs, the decrease being approximately 2 per cent for each per cent of added fat. The added fat had a higher value than the usual estimated net-energy value.

1507. Minerals.—The requirements of poultry for calcium and phosphorus are greater than those of the larger farm animals. Special consideration must therefore be given to the amounts of these minerals in making up poultry rations. Salt should be provided for poultry, but the requirement is relatively low.

While it is not generally necessary to give any consideration to manganese in feeding other livestock, a very small amount of manganese supplement must often be added to poultry rations to prevent serious nutritive deficiencies. In iodine-deficient areas, it is advisable to use iodized salt for poultry, instead of ordinary salt, or to include in the ration some feed that serves as an iodine supplement. The requirements for these and other minerals and also the use of grit and of charcoal in poultry rations are discussed in the following articles.

1508. Calcium.—Poultry need a much higher content of calcium in their rations than do other farm animals.[13] Laying birds need especially large amounts, because egg shells are composed almost entirely of calcium carbonate. The calcium requirement for chicks and growing poultry is also high because of their rapid growth.

It will be noted that in the nutrient requirements stated by the committee of

the National Research Council, 2.25 per cent of calcium is recommended in rations for laying hens and 1.0 per cent in rations for chicks. (**1498**) Rations for growing turkeys should have about 2.0 per cent of calcium. (**1586**) These recommendations are based on numerous experiments that have been conducted to find the optimum calcium content of poultry rations.

For laying hens, a common plan is to include in the mash only enough calcium supplement to provide part of the requirement, and to let the hens have access at all times to oyster shell or limestone grit fed separately. When both mash and grain are fed, from 1.0 to 2.5 per cent of ground limestone or other calcium supplement is generally included in the mash. Even 2.5 per cent will supply less than one-half of the requirement, as high-calcium limestone contains approximately 38 per cent of calcium.

For poultry there should be a suitable proportion, or ratio, between the amounts of calcium and of phosphorus in the ration. This proportion is called the calcium-phosphorus ratio. (**152**) For chicks, it seems most desirable to have about 1.5 times as much calcium in the ration as there is of phosphorus.[30] The calcium-phosphorus ratio is then 1.5 : 1. However rations ranging from 1.0 : 1 to 2.5 : 1 have been used in chick rations without decidedly detrimental results.

Laying hens require a much larger proportion of calcium, because of the great amount in the egg shells. It will be noted that in the table of "Nutrient allowances for chickens," for laying hens more than 3 times as much calcium is advised as of phosphorus. (**1498**)

The great need for calcium in egg production is well shown by a study in Scotland.[31] It was found that at the outset of laying, a pullet's body contains 25 to 30 grams of calcium. Each egg, including the shell, has about 2 grams. Thus, in producing 200 eggs, the pullet must have available more than 13 times as much calcium as there was in her body when she started laying.

A decided deficiency of calcium in poultry rations produces serious results. The egg production of hens is greatly reduced, and many of the eggs have weak shells. For example, in an Ohio experiment the percentage egg production of pullets fell from a daily average of 45 per cent to 20 per cent in 2 weeks when they were fed no calcium supplement.[32] During the entire 46 weeks of the trial, these pullets laid only one-half as many eggs as did pullets receiving ample calcium. Also, 76 per cent of their eggs had weak shells.

It was found in South Carolina investigations that even when the ration had an ample amount of calcium, hens steadily lost calcium from their bodies during the first few weeks after they started to lay.[33] As much as 25 per cent of the entire amount of calcium in their bodies may thus be lost in 6 weeks. Later the hens are able to utilize the calcium in their feed more efficiently, and to regain the calcium store in their bodies without slackening egg production.

An excessive amount of a calcium supplement should not be included in a poultry mash. A considerable excess of calcium interferes with the utilization of manganese, and it may reduce egg production and lower the hatchability of the eggs.[34] When the usual percentage of calcium supplements is included in the mash and hens are provided with oyster shell or limestone grit in addition, there is no danger of their eating an excessive amount of it.

The calcium supplements used most commonly for poultry are high-calcium limestone and oyster or clam shell. Oyster shell is preferred by many poultrymen, but experiments have shown that high-calcium limestone is equally satisfactory, except perhaps in regions where there is a deficiency of iodine.[35] In such areas the iodine furnished by oyster shell may be beneficial, but iodine can also be supplied readily by using iodized salt instead of common salt. Dolomitic limestone, which is high in magnesium carbonate, is not satisfactory for poultry. Other suitable calcium supplements are listed in Chapter VI. (**157**) The calcium in bone meal, defluorinated phosphate, or gypsum (calcium sulfate) can be used

efficiently for growth, but is definitely inferior to calcium carbonate for egg production.

Interesting experiments have been conducted recently with radioactive calcium and phosphorus to study the assimilation of these minerals and their transference to the egg and from the egg to the chick.[36]

1509. Phosphorus.—It is shown in the table of *"Nutrient allowances of chickens"* earlier in this chapter that rations containing 0.6 per cent total phosphorus are advised for chicks, growing chickens, and hens. (**1498**) In recent experiments somewhat less phosphorus has been satisfactory for growing chickens and for hens, when there was a proper calcium-phosphorus ratio and an ample amount of vitamin D.[37]

For chicks, the greater part of the phosphorus should be in inorganic form, because they do not well assimilate phosphorus in the form of phytin. (**151**) As stated in the footnote following the table, in a ration for chicks there should be at least 0.45 per cent of inorganic phosphorus.

As much as three-fourths of the phosphorus in the grains and the by-products of grains and other seeds may be phytin phosphorus. It is therefore important that part of the phosphorus be supplied in readily available forms.

Older chickens make somewhat better use of phytin phosphorus than do chicks, but a part of the phosphorus in rations for growing chickens and for hens should be in inorganic form.[38] However, the percentage of inorganic phosphorus they need has not been definitely determined.

As stated in Chapter VI, there is less difference in assimilation of phytin phosphorus when there is an abundant supply of vitamin D in the ration. Also, the assimilation of phytin phosphorus may be improved when the ration contains natural, unheated roughages, such as green forage or sun-cured alfalfa meal. Such roughage contains an enzyme which can split phosphorus off from the phytin.

The phosphorus in meat scrap, tankage, fish meal, and dairy by-products is largely in inorganic form and is readily available to poultry.

When meat scrap, tankage, fish meal, and dairy by-products are used as the chief protein supplements in poultry rations, there will usually be sufficient phosphorus, without the addition of any special phosphorus supplement. On the other hand, if soybean oil meal or other protein supplements of plant origin furnish most of the protein, it will be necessary to add phosphorus, as well as calcium.

Some years ago bone meal was often added to chick mashes in which meat scrap, tankage, or fish meal was the chief or only protein supplement. Experiments proved, however, that the addition of a phosphorus supplement to such a ration was decidedly detrimental. Because of the excessive amounts of phosphorus and calcium, the manganese in the ration was rendered unavailable, and perosis, or slipped tendon, was produced.

Information is given in Chapter VI concerning the value of various phosphorus supplements, and about the injurious effects produced by rock phosphate or other phosphates that contain a dangerous amount of fluorine. (**158–169**)

Properly made bone meal is an excellent phosphorus supplement for poultry. In experiments to compare various sources of phosphorus, defluorinated phosphates and dicalcium phosphate have also ranked high in availability.[39] When used as the only phosphorus supplement, ground rock phosphate or colloidal phosphate (soft phosphate with colloidal clay) has been poorly utilized in some experiments. Colloidal phosphate may give better results when used in combination with bone meal.

1510. Salt.—Salt is needed by poultry, but the requirement is relatively small. In the report of the committee of the National Research Council on the nutrient requirements of chickens, the addition of 0.5 per cent of salt to rations for chickens was recommended. (**1498**)

However, New York experiments with chicks have shown that the addition of only 0.25 per cent salt to an or-

dinary ration for chicks was sufficient.[40] Including 0.5 per cent of salt tended to make the droppings moist. A range of 0.25 to 0.5 per cent in added salt is therefore given in the table presented earlier in this chapter.

If hens or growing chickens are fed scratch grain and mash separately, the mash should contain about 1 per cent of salt. When meat scrap, tankage, or fish meal is used as the chief protein supplement, only 0.5 per cent of salt need be added to the mash, because these feeds contain more salt than do the grains or the by-products of grains and other seeds.

Too great an amount of salt is injurious to poultry. In a Pennsylvania trial adding 5 per cent of salt to a ration for chicks caused high mortality, and in a North Dakota test a ration having 4 per cent was detrimental to turkey poults.[41] In this test rations with 6 per cent or more of salt caused heavy death loss.

1511. Manganese; prevention of perosis, or slipped tendon.—It has been shown in Chapter VI that poultry have special needs for manganese. (**180**) A deficiency of manganese is the chief cause of perosis, or slipped tendon, in chicks, in which the legs are deformed by the slipping of the Achilles' tendon from the proper position. Usually only one leg is affected, but sometimes both are deformed. The deficiency also causes a shortening and thickening of the long bones of the legs and wings.

Perosis may also be caused by a deficiency in experimental rations of certain B-complex vitamins—choline, biotin, or folic acid.

Manganese is needed for egg production and good hatchability. Experiments have shown that if hens are fed a ration deficient in manganese, egg production is decreased, the strength of the egg shells is lowered, and the hatchability of the eggs is greatly reduced.[13] Many chicks that fail to hatch are characteristically deformed, with parrot-like beaks and short legs and wings.

Deficiencies of manganese are most apt to occur in poultry kept in strict confinement, with no access to pasture or sunlight. Plymouth Rocks and other heavy breeds apparently require more manganese than do White Leghorns.

Only mere traces of manganese are needed in rations to prevent any deficiencies. It will be noted in the table of "*Nutrient requirements of chickens,*" on a previous page of this chapter, that only 25 milligrams of manganese are needed per pound of feed in starting rations for chicks and 15 milligrams per pound of feed in rations for breeding hens. (**1498**) These allowances are equivalent to 55 parts and 33 parts of manganese per million parts of feed.

It has been pointed out previously that when a ration is high in calcium and phosphorus, the supply of manganese must be greater than otherwise, because the assimilation of manganese is reduced. This is apparently because of the formation of compounds in which the manganese is unavailable. It is believed that these recommended allowances are ample, even when there is a liberal supply of calcium and phosphorus in the ration.

A deficiency of manganese is not apt to occur when there is considerable wheat bran or wheat middlings in the ration, for they have a good content of the mineral. Rice bran is very high in manganese, and fish meal, soybean oil meal, and alfalfa meal have much more than do corn, barley and the grain sorghums.

To guard against a possible deficiency of manganese, one-quarter pound of manganese sulfate is now generally added to each ton of formula mash to be fed without additional grain, and one-half pound per ton to mashes to be fed with grain.

1512. Iodine.—In areas deficient in iodine, goiter (enlarged thyroid gland) may occur in poultry, but egg production and health of the fowls are not generally affected appreciably. (**170**) However, in such areas, it is wise to use iodized salt instead of common salt for poultry, or to include in the ration a feed such as fish meal, that serves as an iodine supplement.

It will be noted that in the table of "*Nutrient requirements of chickens*" an

allowance of 0.5 milligram of iodine per pound of feed is recommended. (1498) This is only 1.1 parts of iodine per million parts of feed. In recent experiments by the Indiana Station a very much smaller trace of iodine (only 0.07 part per million parts of feed) produced normal growth of chicks.[42]

Several experiments have been conducted in this country and in Europe to find whether there was any advantage in adding iodine to ordinary poultry rations in other regions than those known to be deficient in iodine. Ewing concludes from a review of such experiments that in the experiments conducted in this country there has been no evidence of a benefit to poultry from such an addition of iodine, and that in European experiments the data have been conflicting.[43] Feeding a ration high in iodine definitely increases the iodine content of eggs.

1513. Other minerals.—The requirements of chicks for potassium and magnesium are stated in the table of *"Nutrient requirements of chickens."* (1498) However, there is no lack of either of these minerals in ordinary poultry rations. Neither does there seem to be a deficiency of cobalt, iron, copper, or sulfur in practical poultry rations.

It is pointed out later that recent experiments have shown that one of the unidentified factors required by chicks is an unrevealed trace mineral or a combination of such minerals. (1528)

1514. Grit.—Grit aids in the grinding of whole grain or other coarse feed in the gizzard. Also, crushed oyster shell or limestone grit furnishes calcium as it dissolves. Some limestone is too soft to be an effective grinding agent. Insoluble grit, such as granite or quartz grit, serves as grinding material, but not as a calcium supplement.

Experiments have shown that grit should be supplied laying hens, and that it is best to furnish hard grit in addition to limestone grit or oyster shell. In Ohio experiments, supplying layers with hard grit in addition to limestone grit or oyster shell increased the egg production 9.6 per cent and reduced the feed requirement per dozen eggs 7.1 per cent.[44] Because of the small amount of hard grit consumed, the addition resulted in a material saving in the cost of egg production. If an all-mash ration is fed layers, grit may not be necessary. Screened gravel of suitable size is a satisfactory form of grit.

Experiments have shown that there is little or no advantage in supplying grit for chicks up to 4 to 8 weeks of age when they are fed the usual type of ground mash.[45] After that, there was some benefit from supplying grit, especially if the mash was coarsely ground, and it was desirable to supply hard grit in addition to limestone grit or oyster shell.

1515. Charcoal.—Years ago it was a common practice to add charcoal to poultry rations as an absorbent of gases and a corrective of diarrhea. Experiments have shown, however, that there is no advantage from adding it to ordinary rations.[13]

In fact, because of the absorptive and adsorptive power of charcoal, adding it to a ration may produce a vitamin deficiency, unless the ration contains a very abundant supply of vitamins. (182) Also, because of this effect, charcoal tends to absorb xanthophyll and other yellow pigments in the feed, and to produce pale shanks and skin.

1516. Vitamins.—Except for poultry which are on good pasture or which are fed plenty of fresh green forage, it it necessary to give much more attention to their vitamin requirements than in feeding cattle, sheep, or horses. This is due to four factors.

First, rations for poultry consist chiefly of grains and other concentrates, with very little roughage. Second, there is but little synthesis of B-complex vitamins in the digestive tract of poultry. Third, the vitamin requirements of poultry, especially for vitamin A, vitamin D, and riboflavin, are much greater, per pound of live weight, than those of other farm animals. Fourth, in addition to the vitamins which have been identified, poultry require certain unidentified vitamins or factors.

The requirements of poultry for the

various vitamins and for the unidentified vitamins or factors are discussed in the articles which follow.

1517. Vitamin A and carotene.—A liberal supply of vitamin A or carotene is needed for normal growth, also for health, even of mature fowls, and for satisfactory egg production. Poultry are about equal to rats in the efficiency with which they utilize carotene as a source of vitamin A. One U.S.P. Unit (United States Pharmacopoeia Unit) supplied in the form of carotene therefore has approximately the same value as an I.U. supplied in the form of vitamin A. (**194**) As has been pointed out previously, other farm animals use carotene less efficiently than they do vitamin A.

A part of the vitamin A value in poultry rations is often supplied by fish liver oils or other animal sources that furnish true vitamin A. For this reason and also because of the approximately equal value of an International Unit in the form of vitamin A and of carotene, the requirements of poultry are generally stated in terms of International Units of vitamin A value. On the other hand, the requirements of other livestock are commonly given in milligrams of carotene, since carotene usually furnishes all the vitamin A value in their rations.

It will be noted in the table of "*Nutrient requirements of chickens*" that the committee of the National Research Council gives the vitamin A requirement of chicks and growing chickens as 1,200 U.S.P. Units per pound of feed. (**1498**) The requirement of laying hens and of hens producing hatching eggs is given as 2,000 U.S.P. Units per pound of feed.

It is important to bear in mind that in this revised statement of requirements by the committee no margins of safety are included, to cover losses of vitamin value during feed processing and storage and to cover variations in vitamin A content of various lots of the same kind of feed. In making up poultry mashes, it is necessary to provide a considerably higher initial vitamin A content, to make up for the considerable loss of the vitamin A value that may occur in storage of feed. (**195**) This loss is much reduced by including an approved antioxidant in the mash.

In the previous report of the committee of the National Research Council, instead of stating the minimum requirements, recommended allowances were given, which included considerable margins of safety. In that report, allowances of 2,000 U.S.P. Units of vitamin A value per pound of feed were recommended for starting and growing chicks, and 3,300 U.S.P. Units per pound of feed for hens. These allowances seem to provide a sufficient margin of safety in making up practical rations. Roosters apparently need much less vitamin A value than do layers.

Numerous experiments have been conducted to determine the minimum or the optimum amounts of vitamin A value for chicks, growing chickens, and for laying hens.[13] In these studies a vitamin A content somewhat lower than the requirements now stated by the committee has generally been satisfactory, except for hens producing hatching eggs. For example, the actual requirement of chicks to 8 weeks of age has been only 500 to 800 U.S.P. Units of vitamin A value per pound of feed.

Laying hens require a higher content of vitamin A value in their feed in very hot weather than when it is cooler.[46] This is chiefly because they then consume less feed.

It is especially important to have an ample supply of vitamin A in the rations of breeding hens, because the amount of vitamin A in eggs depends on the vitamin A value of the ration. If the hens are supplied with only a sufficient amount for satisfactory market egg production, the vitamin A content of the eggs may not be great enough to provide an optimum supply for the developing chicks. For this reason, some investigators recommend a more liberal supply for breeding hens than is needed for the production of market eggs.

From the standpoint of the consumer, rations having an ample supply of vitamin A are highly desirable for all laying hens, because of the higher vitamin content of the eggs.

If poultry are on pasture or are supplied with fresh green feed, they will have an abundance of vitamin A, because of the high carotene content of green forage. (**196**) When they get no fresh green feed, care must always be taken to provide sufficient vitamin A value.

To insure an adequate supply of vitamin A, a sufficient amount of carotene or vitamin A supplement should be included in poultry mashes. Alfalfa meal of good quality not only supplies carotene, but it also furnishes vitamin K and it helps furnish B-complex vitamins, including one of the unidentified vitamins. (**1228**)

Synthetic vitamin A is now the cheapest source of vitamin A for formula feed manufacturers, but it does not supply the other vitamins furnished by alfalfa meal. Fish liver oils and concentrates commonly furnish not only vitamin A, but also vitamin D_3.

When chicks are fed a ration severely deficient in vitamin A, symptoms of the lack will begin to appear in about 3 weeks. Growth is greatly retarded, and the chicks show general weakness, emaciation, staggering gait, and ruffled plumage. The eyes also become watery and inflamed. The resistance to infection is reduced and mortality is greatly increased. In older birds the eye symptoms often become more acute, and in advanced stages the sight may be destroyed. A deficiency of vitamin A often causes symptoms resembling roup, the trouble being called "nutritional roup." In this there is a sticky or cheesy discharge from the eyes and a sticky discharge from the nostrils.

1518. Effect of feed on color of egg yolks and body tissues.—Certain yellow substances which are transferred from the feed greatly affect the color of egg yolks and of the shanks, beaks, skin and body fat of poultry. The effect is chiefly produced by xanthophylls, which are somewhat similar to carotene, but which have no vitamin A value. (**197**)

Xanthophyll is transferred to egg yolks and to body tissues to a much greater extent than is carotene. Most of the carotene that is assimilated by poultry is converted in the body to vitamin A, which has but very little yellow color. Carrots and sweet potatoes, which are rich in carotene but which have relatively little xanthophyll, do not therefore have a marked effect on the color of egg yolks or body tissues.

The condition in poultry is therefore much different from that in cattle, in which yellow color in body fat or in milk is due to unchanged carotene assimilated from the feed, and not to xanthophyll.

Experiments have shown that a marked yellow color in egg yolks and body tissues is produced by green feeds, by good alfalfa hay or other legume hay, and by yellow corn and by-products made from yellow corn, such as corn gluten meal, corn gluten feed, and hominy feed. The other grains and the other common concentrates which are not made from yellow corn tend to produce light-colored yolks and body tissues. Yellow pigmentation is decreased by cod-liver oil and certain other fish oils, and also by meat scrap, fish meal, soybean oil meal, charcoal, or sulfur in the ration.

Because of the difference in the effect of various feeds, it is possible to regulate the color of egg yolks and of the shanks and skin of market poultry to suit the local demands, which vary in different regions. For example, light-colored yolks are preferred in the New York City market. Though alfalfa meal tends to produce a yellower color in egg yolks, the yolks are not too yellow, if not over 5 per cent of alfalfa meal is used in the laying mash.

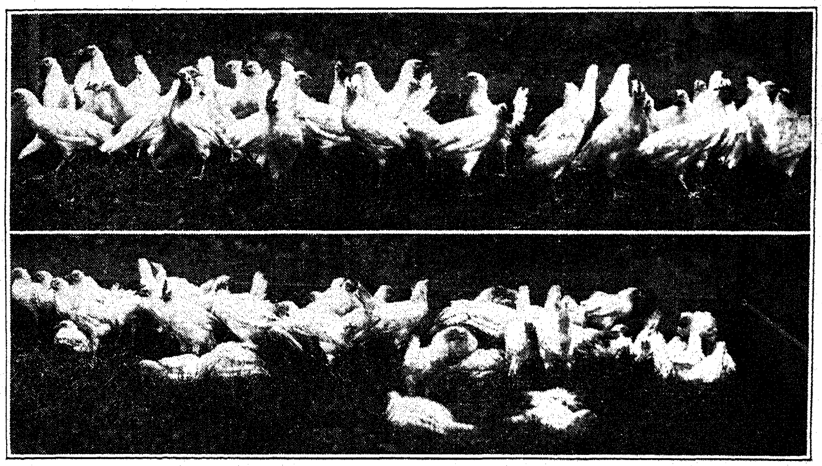
Certain feeds produce an undesirable color in egg yolks. If a ration for laying hens has more than about 5 per cent of ordinary cottonseed meal, the yolks are apt to develop an olive-green or brown color on storage, or to have dark spots. (**819**) A greater amount of low-gossypol cottonseed meal can be included in a ration without producing this discoloration. Also, adding 0.5 per cent of an iron salt to the feed seems to prevent it. (**812**) Shepherd's purse and penny cress, weeds which are members

of the mustard family, tend to produce olive-green yolks.

1519. Vitamin D; sunlight.—Poultry need much greater amounts of vitamin D than do the larger farm animals, per pound of liveweight or per pound of feed consumed. A deficiency of vitamin D causes poor growth, lameness, and other characteristic symptoms of rickets in chicks. (153) The first symptom of vitamin D deficiency in laying hens is the production of thin-shelled eggs, followed very shortly by decreased egg production. Hatchability is also greatly reduced. In laying hens suffering from vitamin D deficiency, the breast bone becomes soft and rubbery, because of withdrawal of calcium and phosphorus. Also, the bones of the legs and wings become fragile and are easily broken. Fowls may lose the use of their legs and squat in a characteristic manner, sometimes called "egg paralysis."

As has been explained in Chapter VII, the form of vitamin D in sun-cured forage and irradiated yeast, called vitamin D_2, has a very low efficiency for poultry, in comparison with the efficiency for man or four-footed animals. (202) On the other hand, vitamin D_3, which is the form in fish liver oils and in activated animal sterol, is equally effective for poultry and for other animals.

Sufficient exposure to the ultra-violet rays of sunlight which has not passed through window glass is effective in meeting the vitamin D requirements of poultry, just as in the case of other livestock. (201) When poultry do not have ample exposure to direct sunlight, it is essential to include a vitamin D supplement in the ration, or possibly to furnish the vitamin by irradiating the birds with ultra-violet light.



EFFECT OF LACK OF VITAMIN D ON CHICKS

The thrifty chicks in the upper illustration were raised in confinement, but cod-liver oil was included in the ration to furnish vitamin D. The chicks in the lower illustration received no cod-liver oil. They grew poorly, and many are severely affected with rickets. Some are paralyzed. (From Heuser and Norris, New York Station.)

The vitamin D requirements of poultry are expressed in International Chick Units (I.C.U.) of vitamin D_3. In the table of "*Nutrient requirements of chickens*" given earlier in this chapter, the requirement per pound of feed is 90 I.C.U. for starting chicks and growing chickens and 225 I.C.U. for hens. These are the estimated minimum requirements and do not include any margin of safety.

Experiments have shown that good growth and satisfactory egg production are secured on these amounts of vitamin D in rations when chickens have no ex-

posure to sunlight, provided that there are proper amounts of calcium and phosphorus.[13] However, rapid-growing strains of chicks seem to need considerably more of the vitamin for maximum gains and feed efficiency.[47]

Because of this and to provide ample margins of safety, in most of the rations recommended by the agricultural college poultry scientists greater amounts of vitamin D are included.[48] In mashes for chicks 270 to 300 or more I.C.U. per pound of feed are generally advised, and in mashes for laying hens, to be fed with grain, 500 to 800 I.C.U. per pound of mash.

When hens are fed, free-choice, mash and whole grains, especially corn or wheat, they sometimes eat so much of the grain that a deficiency of vitamin D occurs, unless the mash is well fortified with the vitamin.[49] When egg production drops for no other apparent reason, or when there are a considerable number of weak-shelled eggs, a deficiency of vitamin D may be suspected. If the trouble is due to this lack, it can be corrected within 3 weeks by supplying an ample amount of vitamin D supplement.

To avoid danger of a fishy flavor in meat, it is desirable to omit fish oils from rations for chickens during at least the last 2 weeks before they are sold for meat, and for not less than 8 weeks in the case of turkeys.

Instead of using a vitamin D supplement in rations for confined poultry, the vitamin may be supplied by exposing the birds to irradiation with ultraviolet light produced by sunlamps. Experiments have shown that sufficient irradiation with such lamps is as effective as adding a vitamin D supplement to the ration.[50] Which method will be more economical will depend largely on the local rate for electricity.

Relatively short exposure to direct sunlight may provide enough vitamin D for chicks. In Texas trials, only 1 hour of direct sunlight per week furnished sufficient vitamin D for chicks fed rations having ample calcium and phosphorus.[51]

Sometimes glass substitutes which permit the passage of more or less ultraviolet light are used in poultry houses instead of window glass. Unless carefully handled most such substitutes are short lived, and unless they are kept clean and taken out in summer they lose their effectiveness.

1520. Riboflavin.—Riboflavin is by far the most important of the B-complex vitamins in feeding poultry. This is because poultry have very high requirements for it. Also, there is not much synthesis of riboflavin by bacteria in the digestive tract, such as occurs in ruminants.

A deficiency of riboflavin causes poor growth of chicks and a characteristic paralysis of the legs and feet, known as "curled toe paralysis," or "nutritional paralysis." A chick suffering from this paralysis is shown in the illustration on Page 137. In laying hens a deficiency of riboflavin results in low hatchability of eggs. Considerably more riboflavin is needed for good hatchability than is required for egg production and maintenance of health.

It will be noted that the table of *"Nutrient requirements of chickens"* gives the following requirements of riboflavin per pound of ration: For chicks up to 8 weeks of age, 1.3 milligrams per pound of feed; for growing chicks from 8 to 18 weeks, 0.8 milligram; for laying hens, 1.0 milligram; and for breeding hens producing hatching eggs, 1.7 milligrams. (1498) These amounts are the estimated minimum requirements and do not include any margins of safety.

The riboflavin content of various feeds is discussed in Chapter VII. (212) The amounts of riboflavin in all important feeds are shown in Appendix Table V, so far as data are available.

Poultry on good pasture have plenty of riboflavin, for all fresh green forage has an abundant amount. For poultry not on pasture, care must be taken to supply enough riboflavin. This may be done by using feeds rich in riboflavin, such as milk by-products, alfalfa meal, or distillers solubles, or by adding to the ration a special vitamin supplement, such as

certain fermentation by-products or synthetic riboflavin.

Experiments have shown that synthetic riboflavin, which is now produced commercially, is just as effective as the natural riboflavin in feeds for supplying riboflavin.[13] However, synthetic riboflavin does not furnish other B-complex vitamins or unidentified vitamins, which are supplied by such feeds as milk by-products and alfalfa. For the best results, synthetic riboflavin should therefore be used in combination with feeds that furnish ample amounts of these other vitamins.

1521. Thiamine.—Thiamine is required by all poultry, but ample amounts are supplied by ordinary rations. A deficiency of thiamine in restricted rations causes loss of appetite, emaciation, poor digestion, general weakness, heart abnormalities, and frequently convulsions because of nerve degeneration. (211)

1522. Niacin.—Young chicks require more niacin per pound of feed than do older chicks or hens. This is apparently due to some synthesis of niacin by bacterial action in the digestive tract of older birds.

The committee of the National Research Council gives the requirement of niacin for chicks up to 8 weeks of age as 12 milligrams per pound of feed. (1498) Most rations for chicks that are otherwise satisfactory contain fully as much niacin as this.

In recent Wisconsin studies chicks from 6 weeks to 10 weeks of age were found to require only 3.5 to 6.0 milligrams of niacin per pound of feed.[52] The requirements of older chickens have not yet been determined. Since niacin can be formed in the body from tryptophan, a diet containing ample tryptophan reduces the niacin requirement.

A deficiency of niacin in purified experimental diets for chicks causes "black tongue," characterized by inflammation of the tongue and mouth cavity. Also, growth is retarded, feather development is poor, and occasionally scaly dermatitis of the feet and skin result. In turkey poults and sometimes in chicks, an experimental diet deficient in niacin causes a hock disorder similar to perosis.

1523. Vitamin B_{12}.—Vitamin B_{12} is essential for the growth of chicks and for hatchability of eggs. However, only an exceedingly small amount of the vitamin is needed. The special committee of the National Research Council in their report on *"Nutrient Requirements of Poultry"* states the tentative requirement of chicks to 8 weeks of age as only 0.004 milligram of vitamin B_{12} per pound of feed.[8] The tentative requirement of breeding hens producing hatching eggs is given as 0.002 milligram per pound of feed.

If hens receive a ration adequate in vitamin B_{12}, there is a marked carry-over of the vitamin in the egg to the chick.[53] On the other hand, when hens receive a ration deficient in vitamin B_{12}, it may cause high mortality in very young chicks.

More vitamin B_{12} is needed by hens kept on wire than for hens on litter, because the vitamin is synthesized by bacterial action in the feces in the litter. Heavy breeds of hens seem to require a larger amount of the vitamin than do Leghorns.

It has been pointed out in Chapter VII that much of the benefit from adding a supplement of animal origin to an all-plant-product ration for poultry is due to the vitamin B_{12} thus supplied. (220)

Before vitamin B_{12} was discovered and identified, the term *animal protein factor* was used for the factor or factors supplied by such supplements as fish meal, fish solubles, meat scrap, tankage, and dairy by-products. It is now known that these supplements furnish not only vitamin B_{12}, but also unidentified vitamins or factors, which are discussed later. (1528)

The approximate amounts of vitamin B_{12} in various feeds are stated in Appendix Table Vb, so far as data are available. Concentrated vitamin B_{12} feed supplements and antibiotic-vitamin B_{12} feed supplements are available commercially, which contain guaranteed amounts of vitamin B_{12}.

1524. Other B-complex vitamins.—Pantothenic acid, choline, pyridoxine, folic acid (or folacin), and biotin are all

required by poultry. These vitamins are discussed in some detail in Chapter VII, and the effects of a deficiency in experimental rations are stated.[13] (214–219) The amounts of each of these vitamins required by young chicks are stated in the previous table of *"Nutrient requirements of chickens."* (1498) The requirements of hens are also given in this table, so far as data are available.

Fortunately, most poultry rations that are adequate in other nutrients furnish sufficient amounts of each of these vitamins.

Pantothenic acid and choline supplements are added to some formula mashes for chicks, for broilers, or for hens producing hatching eggs, to make sure there will be no possible deficiency of these vitamins. As stated in Chapter VII, betaine can partially replace choline in the diet. (218)

1525. Yeast.—Brewers' dried yeast and other forms of yeast are rich in riboflavin and other B-complex vitamins, and may be used to supply these vitamins in poultry rations.

In most of the experiments in which dry yeast has been added to poultry rations containing an ample supply of riboflavin and other B-complex vitamins, or in which such rations have been fermented with yeast, there has been no benefit from the use of yeast.[54]

1526. Vitamin E.—Detailed information is given in Chapter VII concerning vitamin E, or tocopherols, in livestock feeding. (223) As there stated, a lack of vitamin E in experimental rations purposely made deficient in the vitamin causes the disease called nutritional encephalomalacia, or "crazy chick disease." The chick suddenly becomes prostrated, lying with legs outstretched and toes bent. The head is drawn back and often twisted to the side. Before the final stage, its movements are frequently incoordinated.

In mature fowls, a prolonged vitamin E deficiency in an experimental ration causes lowered hatchability of eggs and sterility of males.

The definite requirements of poultry for vitamin E have not yet been determined accurately, because most good rations seem to supply a sufficient amount of the vitamin. According to Titus, the requirement of vitamin E by chicks is probably not less than 6 milligrams per pound of feed, and a satisfactory allowance is 9 milligrams.[55]

In Connecticut experiments chicks fed an experimental ration having only 3 milligrams of vitamin E per pound made good growth and no nutritional encephalomalacia developed.[56] However, adding 2 per cent of fish oil to this ration as a stress factor produced heavy mortality from this disease. This was due to the destruction of vitamin E by the highly unsaturated fats in the fish oil.

The nutritional encephalomalacia was prevented when 0.05 per cent of an antioxidant (diphenyl-p-phenylenediamine, DPPD) was added to the ration, along with the fish oil. This prevented the destruction of vitamin E.

New York studies have shown that on a ration low in vitamin E, White Leghorn chicks are more resistant to nutritional encephalomalacia than are Rhode Island Red or Barred Plymouth Rock chicks.[57]

Information is given in Chapter VII concerning the occurrence of vitamin E in different kinds of feeds. (223) The approximate content in various feeds is given in Appendix Table Vd, so far as data are available. If there has been trouble from nutritional encephalomalacia on a practical ration, a feed should be added that is rich in vitamin E, or else a tocopherol concentrate. DPPD or another suitable antioxidant should also be included in the mash, to prevent the destruction of vitamin E during storage.

1527. Vitamin K; hemorrhagic disease.—The need by chicks for vitamin K to preserve the clotting power of the blood is discussed in detail in Chapter VII. (225) A lack of this vitamin in the feed of chicks greatly delays the clotting time of the blood and may produce serious hemorrhagic disease. Chicks fed a ration deficient in vitamin K may bleed to death from any injury or bruise which causes rupture of blood vessels. In severe vitamin K deficiency, hemorrhages may

occur in any part of the chick's body. These hemorrhagic conditions seem to be the only symptom of the lack of the vitamin.

Although this trouble is readily produced in chicks fed an experimental ration low in the vitamin, symptoms of deficiency are not caused when hens are fed the same ration. This is probably because more vitamin K is synthesized by bacterial action in the intestine of the older birds. However, if hens are fed a ration deficient in vitamin K, chicks hatched from their eggs may bleed seriously from minor wounds, such as wing banding.

In the report on *"Nutrient requirements of chickens"* the special committee of the National Research Council gives the tentative requirement of vitamin K for chicks to 8 weeks of age as 0.18 milligram per pound of feed.[8] Only 1 to 2 per cent of alfalfa meal of good quality usually furnishes ample vitamin K in poultry rations, even for chicks.[58]

However, as is stated in Chapter VII, the requirement of the vitamin is considerably increased if there is added to the ration a high level of certain drugs, such as sulfaquinoxaline (for coccidiosis control) or arsonic acid derivatives (as a growth stimulant). Hemorrhagic trouble may then occur in chicks on a ration that would be otherwise satisfactory.

In such cases the trouble can be prevented by increasing the percentage of alfalfa meal, by adding green feed, or by adding to the ration menadione or menadione sodium bisulfite (a water-soluble form of menadione). Such an addition should also be made to a high-energy ration for chicks which contains no alfalfa meal, or an insufficient amount to prevent hemorrhagic disease.

1528. Unidentified vitamins or factors.—Recent investigations have shown that in addition to the known and identified vitamins, certain unidentified vitamins or factors are also required by chicks and turkey poults. These have been discussed in Chapter VII. (222)

Older birds have less need of these vitamins or factors, probably because certain amounts are synthesized by bacterial action in the intestine. However, if hens or turkeys producing hatching eggs are continuously fed a ration deficient in these substances, the chicks or poults from their eggs will be depleted in these compounds. They will then not make normal growth unless their ration has ample amounts of these unidentified substances.

For this reason, in the investigations to study these mysterious substances, chicks or poults are generally used which are from dams that have been fed rations lacking these vitamins or factors. Chicks or hens kept on wire show a much greater need of these substances than do those kept on litter, especially deep litter. This is undoubtedly because of the synthesis of these compounds in the litter.

Painstaking experiments have shown that at least 3 or 4 unidentified vitamins seem to be required by chicks.[59] In addition, an unknown trace mineral or combination of minerals is evidently needed.

One of the unidentified vitamins, called the fish solubles factor, or the liver factor, is supplied in largest amounts by fish solubles, fish meal, liver meal, penicillium mycelium meal, and some other fermentation products.[60] Meat scrap has somewhat less, and there is a still smaller amount in dairy by-products.

A second unidentified vitamin, called the distillers solubles factor, is furnished by grain or molasses distillers solubles and yeast.[61]

A third, called the grass juice factor, or the alfalfa factor, is supplied by fresh green forage, dairy by-products, brewers' dried yeast, and alfalfa meal.[62] Soybean oil and grain or molasses fermentation solubles have small amounts.

Whey apparently furnishes both the grass juice factor and the fish solubles factor. Some investigators consider that the factor present in dried whey, other dairy by-products, and certain other feeds is a distinct factor.[63]

In recent New York and Texas studies chicks from hens fed a ration deficient in unidentified vitamins or factors were given purified experimental diets supplying ample amounts of all known nu-

tritive essentials.[64] The chicks were kept on wire to prevent their obtaining the unidentified substances from the feces.

The addition of dried distillers solubles produced a marked increase in growth rate of these chicks. Surprisingly, when the ash of distillers solubles was added to the experimental diet, the growth was also increased, although to a considerably less extent than by the distillers solubles. This indicated that part of the benefit from the addition of distillers solubles was due to some trace mineral or to a mixture of minerals supplied by the distillers solubles. In the New York studies, this effect was not produced by the addition of any of the recognized essential trace minerals, or of several other minerals tested.

In a recent Illinois experiment the ash of fish meal improved the growth rate of chicks fed a purified diet lacking unidentified vitamins or factors.[65] On the other hand, in another Illinois trial the ash of distillers solubles did not consistently increase the growth of chicks fed such a diet, while distillers solubles itself uniformly improved growth.[66]

The greatest improvement in growth of chicks is apparently not produced unless all of the unidentified vitamins or factors are present in the diet. It is therefore important to see that a mash for chicks has sufficient amounts of the feeds or supplements that furnish these essentials.

The amounts of these unidentified vitamins or factors required for maximum growth by chicks have not been determined, because these substances have not been separated and identified. The example rations for poultry in Appendix Table VII show the approximate amounts needed of the feeds which supply these vitamins or factors.

1529. Anti-gizzard-erosion factor.—Sometimes the lining of the gizzard of chicks becomes eroded in spots, apparently because of a nutritive deficiency.[67] Unless the erosions are severe, the growth of the chicks does not seem to be affected.

If the ration contains sufficient of certain feeds, this trouble is largely prevented. The anti-gizzard-erosion factor is supplied by alfalfa meal, green forage, wheat bran and wheat middlings, oats and oat hulls, and liquid skimmilk, buttermilk, or whey, but apparently not by dried dairy by-products. Bile and cholic acid, a bile ingredient, are especially rich in the factor. There seems to be less of the trouble if the ration has ample vitamin B_{12}.

1530. Net-energy values, or productive-energy values.—The only extensive experimental data concerning the net-energy values of feeds for poultry were secured by Fraps and associates at the Texas Station some years ago in investigations with chicks.[68] These experiments were conducted by the carcass-analysis method described in Chapter II. (72) In this method the bodies of chicks are analyzed after being fed the experimental rations for several weeks. From the amounts of protein and fat stored in the body, the storage of energy is determined, and to this amount of energy is added the net energy used for maintenance.

In this manner the net-energy values of a considerable list of feeds were determined directly. From the data thus secured, Fraps computed *production coefficients* for computing the net-energy values of feeds from the chemical composition, and published a table giving these net-energy values for many feeds. He used the term *productive energy* instead of net energy for these values, which are the same as net-energy values.

For poultry feeding, net-energy or productive-energy values are now most commonly stated in terms of Calories (large calories) per pound of feed. For other stock, net-energy values are usually expressed in terms of therms per 100 lbs. of feed (1,000 Calories equal 1 therm.)

Recently, Titus has computed and published productive-energy values for the important poultry feeds, by using Fraps' data and later data concerning the composition of feeds and their digestibility by poultry.[69]

The original Fraps' productive-energy values for the most important poultry feeds and the revised values com-

puted by Titus are given in Appendix Table XI.

The investigations by Fraps and associates showed that corn, wheat, the grain sorghums, and barley had even higher productive-energy values for chicks than these grains have for ruminants. Thus, ground dent corn of Grade No. 2 had a productive-energy value of 1,092 Calories per pound, ground wheat a value of 1,013 to 1,024 Calories per pound, and ground grain sorghums fully as high values as that of corn.

In contrast to these grains, which are low in fiber and high in digestibility, were feeds high in fiber or otherwise poorly digested by poultry. Thus, oat hulls or cottonseed hulls supplied no productive energy to chicks. Alfalfa meal furnished only 261 Calories per pound, and alfalfa stem meal but 185 Calories per pound.

Though dried beet pulp is not very high in fiber, its carbohydrates are digested poorly by poultry, and it supplied but 220 Calories of productive energy per pound. The productive-energy value of wheat bran was only 478 Calories per pound, while that of white shorts was 983 Calories, and that of wheat red dog 1,020 Calories.

Most of the protein-rich supplements had much lower productive-energy values than did the cereal grains. The productive-energy value of 43-per-cent-protein soybean oil meal was 674 Calories per pound; of 43-per-cent-protein cottonseed meal, 694 Calories; and of 50-per-cent-protein meat-and-bone scrap, 724 Calories. Though dried skimmilk and dried buttermilk have a high value for poultry because of the excellent quality protein and the vitamin content, their productive-energy values were surprisingly low, being only 525 Calories per pound for dried skimmilk and 707 Calories for dried buttermilk.

The productive-energy values, or net-energy values, determined by Fraps should be considered as only very approximate. This is because the investigations were conducted before the modern knowledge had been gained concerning the vitamin requirements of chicks. It seems possible or probable that some of the experimental diets used in these studies were deficient in some of the vitamins now known to be essential for maximum growth of chicks.

It has not yet been determined whether various feeds have approximately the same productive-energy values for laying hens as for chicks.

1531. Calorie-protein ratio.—It has been pointed out previously in this chapter that chickens fed a high-energy ration need a slightly higher percentage of protein than do those fed a ration lower in energy. (**1499**) Formula feed manufacturers therefore give attention to the ratio, or proportion, between the Calories of productive energy, or net energy, and the percentage of protein in high-energy mashes.

For example, a chick mash furnishing 900 Calories of productive energy per pound and containing 20 per cent total protein has a Calorie-protein ratio of 45.0 : 1.

From his experiments at the University of Maryland and the results of other investigations, Combs recommends that broiler starter rations should have a Calorie-protein ratio of approximately 42 : 1, and a broiler finishing ration, a ratio from 48 to 50 : 1.[70] For hens laying about 200 eggs a year, he advises a Calorie-protein ratio of 62 : 1, and for hens laying 300 eggs a year, a ratio of 56 : 1.

1532. Metabolizable energy.—Metabolizable energy values of poultry rations or feeds can be determined much more easily than productive-energy values, or even total digestible nutrients. All that is necessary is to find the gross energy content of the daily ration, and to subtract from the gross energy the amount of energy excreted daily in the feces. In poultry there is no appreciable loss of energy in combustible gases produced in the digestive tract, as in the case of cattle. (**76**) Therefore no correction is necessary for this loss.

In recent New York experiments by Hill and Anderson the metabolizable energy values of several feeds and rations have been determined in experiments

with chicks, and also the productive-energy values of certain rations have been ascertained by the Fraps' slaughter method.[71] In these studies it was found that in various experiments the productive energy of the same ration differed widely in different tests. On the other hand, there was good agreement in the metabolizable-energy values determined in different experiments with the same ration.

These studies indicate that metabolizable-energy values are more reliable than productive-energy values for chicks. Therefore, in the future they may prove more useful. Thus far, however, productive energy has been used chiefly by poultry scientists in estimating the energy values of feeds or rations for poultry.

Appendix Table XI gives the metabolizable-energy values for certain feeds, as determined in these New York experiments. Also, this table gives the metabolizable-energy values of other important poultry feeds, computed by Titus from data by Fraps and others.[69]

1533. High-energy rations.—High-energy rations are now commonly used by commercial poultrymen for chicks and broilers, because more rapid growth is produced and less feed is required per pound of gain. The high-energy, or high-efficiency, rations were first developed by Singsen and Matterson of the University of Connecticut for broiler production.[72] Such rations are now widely used not only for broilers, but also for layers and often for rearing pullets.

High-energy mashes for chicks and broilers generally provide 900 or more Calories of productive energy per pound. In order to secure this high-energy content, 50 to 60 per cent or even more of the mash usually consists of corn or corn and wheat. Grain sorghums can be used in place of these grains, with suitable vitamin A supplementation.

Only high-grade, low-fiber dehydrated alfalfa is used in such mashes. To reduce the fiber content and thus increase the energy value, no alfalfa is included in some high-energy broiler mashes. The vitamins that would be supplied by alfalfa must then be furnished by special vitamin supplements.

Since corn is low both in niacin and in tryptophan, supplementary niacin is needed, unless sufficient is furnished by the other feeds. In the Connecticut high-energy formulas for broiler mashes, choline is also added.

Although high-energy broiler mashes necessarily cost more per ton than mashes lower in productive energy, numerous experiments have shown that they are generally more economical and profitable.[73] This is because the gains are more rapid on such a ration, considerably less feed is required per pound of gain, and superior carcasses are produced. The surprising efficiency that can be secured in broiler production on modern high-energy rations, completely supplemented, has been cited previously in this chapter. (1495)

Experiments have also shown that high-energy rations are superior to rations lower in energy for high egg production, especially in cold weather.[74] When it is cold, hens fed a low-energy ration cannot consume enough feed to obtain sufficient energy for continued high egg production and maintenance of their weights.

In recent New York experiments, compared with a high-energy ration supplying 930 Calories of productive-energy per pound, a decrease of 100 Calories per pound in productive-energy increased the amount of feed required per dozen eggs by 12 per cent.[75]

Most experiments have shown that high-energy rations are efficient for raising replacement pullets.[76]

Formulas of high-energy mashes for chicks, broilers, and hens are given in Appendix Table VII.

1534. Fiber.—Because all chickens have very limited ability to digest fiber, their rations must be relatively low in it. Under usual conditions, the fiber content of rations should not be more than about 5 per cent.[77] High-energy mashes generally do not contain more than 4 per cent of fiber.

The growth of chicks fed an experimental diet containing practically no

fiber is increased by adding to it a small percentage of fiber.[78]

Experiments have shown that when as much as 30 per cent of a feed very high in fiber, such as finely-ground oat hulls or peanut hulls, is added to a ration, chicks will eat much more feed and may make nearly normal gains.[79] However, the amount of feed required per pound of gain is greatly increased. Also, on the high-fiber ration considerably less fat is deposited in the body, thus reducing the energy content of the flesh.

If a bulky, high-fiber mash is pelleted, the density is much increased, and the birds can consequently consume more of it. Normal growth can therefore be secured on a pelleted ration which is higher in fiber than would produce good gains, if it was not pelleted. However, much more feed will still be required per pound of gain than on a high-energy ration.

On rations very low in fiber there is more tendency for feather-picking or cannibalism to develop than on rations having more fiber. Including in the ration certain feeds rather high in fiber, especially oats, reduces this tendency, but it of course lowers the energy value.

On high-energy, low-fiber rations it is sometimes necessary to prevent feather-picking by such measures as darkening the house and using ruby-light, or by debeaking the birds (removing the tip of the upper mandibles of the beaks).

1535. Antibiotic feed supplements.—A general discussion of antibiotic feed supplements has been given in Chapter XXIII. (**966**) It is there pointed out that most of the antibiotic supplements on the market not only contain an antibiotic or a mixture of antibiotics, but also supply vitamin B_{12}. A supplement of this kind is called an antibiotic-vitamin B_{12} feed supplement. The effect of such a supplement may be due, of course, both to the antibiotic and also to vitamin B_{12}.

A great number of experiments have been conducted to determine the effects on chickens and also upon turkeys of an antibiotic supplement or of an antibiotic-vitamin B_{12} feed supplement. Most of the studies have been with chicks or broilers, but several experiments have been with hens or growing pullets. Several tests have been conducted with turkeys, but much less information has been secured with ducks or geese.

The increase in growth rate of young birds produced by an antibiotic supplement is greatest for turkey poults, somewhat less, but still important for chicks and goslings, and least for ducks.[80] The use of antibiotic supplements for turkeys, ducks, and geese is discussed in the next chapter.

1536. Antibiotic supplements for chicks and broilers.—In most, but not all, of the experiments with chicks and broilers, the addition to a ration of an antibiotic supplement or an antibiotic-vitamin B_{12} feed supplement has produced an appreciable increase in the rate of growth.[81] The effect has been most marked up to about a month of age.

The growth stimulation has generally been greatest when the supplement has been added to a ration containing no protein supplements of animal origin, or to a ration low in vitamin B_{12} and the unidentified vitamins or growth factors. However, significant growth increases have usually resulted from adding such a supplement to an already excellent ration, containing some fish meal, fish solubles, meat scrap, or dairy by-products.

When the antibiotic supplement has improved the gains, the increase has generally not been more than 10 to 15 per cent. The feed efficiency, or the amount of feed required per pound of gain, has been affected much less than the rate of gain, but it is commonly improved slightly.

The probable causes of the growth stimulation by an antibiotic supplement have been discussed previously.[82] (**966**)

The antibiotic supplements that have been most commonly used for poultry are procaine penicillin, aureomycin (chlortetracycline), terramycin (oxytetracycline), and bacitracin. Streptomycin has been somewhat less effective in most of the tests in which it has been compared with these other antibiotics.[83] Less information is available concerning the

effect of other antibiotics. Some others have been much less effective than those mentioned, and certain ones have produced no growth stimulation or have even depressed gains.

In using an aureomycin, terramycin, or bacitracin feed supplement, usually sufficient is added to the ration to supply about 10 grams of the antibiotic per ton of feed. Less procaine penicillin is needed, only about 4 grams of the antibiotic per ton of feed being enough. To control disease, sometimes a high level of an antibiotic supplement is used (50 grams or more of the antibiotic per ton of feed).

Although an antibiotic supplement has the most marked effect on chicks up to about a month of age, in broiler production, where rapid gains are important, the supplement should be fed continuously.

It has been mentioned earlier that in certain recent experiments chicks kept under practical conditions have responded much less, or not at all, to an antibiotic supplement, while in previous years the growth increase on similar rations had been marked.[84] (**966**) This difference in results may be explained by a reduction in harmful bacteria brought about by the continued use of an antibiotic supplement in the previous years.

In some experiments chicks raised in new quarters, where there have been no birds before, have shown no growth stimulation from an antibiotic supplement.[85] In these trials the antibiotic supplement has increased the growth of other chicks fed the same rations in old quarters. These quarters apparently carried some contamination with undesirable bacteria.

A combination of antibiotics has been no more effective than a single effective antibiotic in most of the experiments in which such a comparison has been made.[86] However, some poultry scientists believe there are fewer failures to obtain a beneficial effect when a combination of antibiotics is used under practical conditions.[87]

The growth of chicks has not been increased in certain trials by implanting an antibiotic pellet under the skin, instead of including the antibiotic in the feed.[88]

1537. Antibiotic supplements for hens or growing pullets.—The results have differed decidedly in the various experiments in which an antibiotic supplement has been added to rations for layers. In most of the trials the egg production has not been increased by adding an antibiotic to a ration which was nutritionally complete.[89]

On the other hand, if hens are fed an all-vegetable-product ration, an antibiotic-vitamin B_{12} feed supplement may appreciably increase both egg production and hatchability. These effects may be due more to the additional B_{12} supplied, than to the antibiotic.[90]

Also, if the egg production of well-bred pullets or hens has declined to an unsatisfactory level on a supposedly adequate ration, an antibiotic supplement may bring a marked increase in egg yield.[91] In such a case, using a high level of the antibiotic supplement is desirable.

The early growth of chicks may be increased when an antibiotic supplement is added to the ration for rearing pullets.[92] This may also result when a ration for hens that is low in vitamin B is supplemented with an antibiotic.[93]

1538. Arsonic supplements.—In the discussion of arsonic supplements in Chapter VII, it was explained that certain derivatives of arsonic acid have generally had an effect somewhat similar to that of an antibiotic, when added to a good ration for chicks or poults.[94] (**967**) In some cases the arsonic supplement even stimulates growth slightly when added to an efficient ration containing an effective antibiotic supplement. Also, the amount of feed required per pound of gain is usually reduced very slightly.

An arsonic supplement may not be beneficial if the level of harmful bacteria or of disease is very low. For example, there was no benefit from adding either an arsonic supplement or an antibiotic to rations for chicks in recent Wisconsin tests.[95] In previous trials these supple-

ments had increased the growth when added to similar rations. Apparently, the continued use of the supplements had reduced the level of harmful bacteria so that a benefit was no longer secured from either type of supplement.

Although the increase in rate of gain and in feed efficiency produced under usual practical conditions by using an arsonic supplement is commonly small, adding the supplement may be profitable. This is because of the very small amount of the supplement needed in the ration. For example, a common rate of addition of certain arsonic supplements is only 0.1 lb. per ton of feed. This addition costs only about 40 cents per ton.

Arsonic supplements commonly added to commercial feeds are arsanilic acid (4-aminophenyl arsonic acid), "3-nitro" (3-nitro-4-hydroxyphenyl arsonic acid), and 4-nitrophenyl arsonic acid. (**967**).

Since the arsonic compounds are toxic in excessive amounts, proper care should be taken to secure even mixing. When properly mixed, meat will not contain excessive amounts, although regulations require that arsonics must not be fed for 5 days prior to slaughter.

Additions of these compounds to rations of growing pullets or of hens has given varied results. In some trials no benefit was secured, while in others, pullets have come into production a few days earlier and hens laid a few more eggs.[96] Eggs from hens fed such compounds contain only trace amounts of arsenic, well below toxic levels.

1538 (a). Furazolidone.—Significant improvements in egg production, with no effect on hatchability and fertility were secured in Arkansas experiments by the addition of dietary furazolidone (N.F. 180) to laying and breeder hen rations, often with a reduction in feed required per dozen eggs. Disease levels present as well as management procedures coupled with the economics of the situation will dictate whether or not such additions are practical.

1538 (b). Enzymes, water treatment of grains.—A recent development is the finding that soaking or adding enzymes to certain cereal grains, such as barley, pearled barley, oats and rye, improves their value for poultry according to work by Washington and Oregon. This discovery is still too new to properly evaluate it.

1539. Surfactants.—Several trials have been conducted during recent years to find whether adding certain surfactants to a ration for chicks would increase the growth.[97] As has been stated in Chapter VII, in most of the tests surfactants have not stimulated growth, or else have been less effective than a suitable antibiotic. (**967**) In trials where the growth has been increased, the effect has usually been after the chicks were 5 to 8 weeks old.[98]

1540. Hormones.—The hormone that has been used most widely in practical poultry production is diethylstilbestrol, a synthetic female sex hormone. (**54**) Administering this hormone, commonly called stilbestrol, to cockerels or roosters a few weeks before slaughter has a feminizing effect.[99] It increases the fatness and tenderness of the meat and improves the market finish. Sometimes the hormone is used for broilers of both sexes during the finishing period.

Cockerels treated with the hormone have some of the characteristics of capons, and are called "caponettes," or "hormonized fryers."

The stilbestrol is administered by implanting under the skin of the head or upper neck a pellet or else a paste which contains the proper dose of the hormone. The hormone is absorbed slowly and therefore only one treatment is needed.

To hasten the fattening, sometimes not only are the birds implanted with stilbestrol, but also 0.15 to 0.20 per cent of thiouracil is added to the ration during the finishing period. This drug slows down the action of the thyroid gland. It thus reduces the rate of metabolism in the body and increases fat deposition.

The feeding of stilbestrol, by adding it to the ration as in the case of fattening cattle, is apparently less effective with poultry than implantation. Such use of stilbestrol has not been authorized by the Food and Drug Administration.

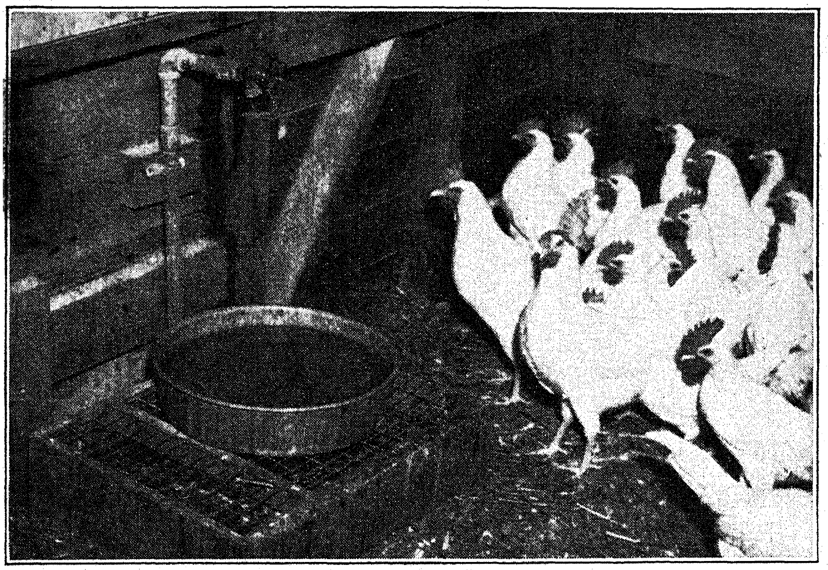
However, including in the ration another synthetic female sex hormone, dienestrol diacetate, has recently been authorized. Feeding this hormone has an effect similar to implanting stilbestrol.

Implanting stilbestrol in breeding stock decreases the egg production of pullets, and it delays sexual maturity of males and decreases the quantity of semen produced.[100] In an Ohio experiment implanting broody hens with stilbestrol broke up the broodiness in most cases.[101]

Adding *thyroprotein,* or iodinated casein, to poultry rations has sometimes been recommended to increase body metabolism. (54) However, in most of the experiments which have been reported, this supplement has not increased egg production or produced a significant increase in the growth of chicks.[102] Thyroprotein supplementation may increase the thickness of the egg shells, but it tends to reduce the body weights of hens.

1541. Water.—A constant supply of fresh, clean water is an essential for all classes of poultry. Because they drink only a small amount at a time, they will not drink sufficient water for good results when given access to it only once or twice a day, which is often done with larger farm animals.

In cold weather some method should be used to keep the water from freezing. Also, there may be a benefit in taking the chill off the water in cold weather, so that hens will drink more.[103]



A Simple Arrangement for Watering Chickens

The platform covered with wire mesh prevents the litter becoming wet around the waterer. (From New York State College of Agriculture, Cornell University.)

The watering arrangement should be so constructed that the birds cannot roost upon it and foul the water with their droppings, and should be high enough to prevent litter being scratched into it. For chicks a vacuum fountain is desirable. The simplest form of such a fountain is simply a jar filled with water and inverted in a shallow pan. As the chicks drink the water from the pan, air enters the jar and water flows out into the pan until the water level rises.

Poultry consume about 2 to 3 lbs. of water per pound of air-dry feed eaten. The water consumption is greater on a

ration high in protein than on one lower in protein.[104] Also, it is greater on a ration containing meat scrap, fish meal, or dried whey than on an all plant-product ration.[105]

The daily water consumption of laying hens will depend on the rate of egg production and the air temperature. Heavy layers require considerably more than poor layers. Hens may drink twice as much water a day in summer as in winter. The amount of water consumed by hens in a year has ranged from about 116 lbs. to 175 lbs. or more in tests that have been conducted.[106]

II. Other Problems in Poultry Husbandry

1542. Preparation of feed.—Poultry, except young chicks, can utilize whole grain efficiently. Therefore the most common method of feeding laying hens and growing pullets is to feed whole grain separately, in addition to a mash made up of ground grain and protein, mineral, and vitamin supplements.

Sometimes layers are fed ear corn or small grain in the bundle, to save shelling or threshing or to force the hens to take more exercise. When grain is thus fed, it is, however, more difficult to know just how much grain the birds are getting, and often they are underfed.

For feeding as scratch grain or in hoppers, corn is often cracked, instead of being fed whole. Heuser advises that when whole corn is to be fed to layers, the growing pullets should be accustomed to whole corn on the range in summer.[30]

Grain should be ground to only a medium degree of fineness for use in poultry mashes. Fine grinding makes the mash less palatable, especially in the case of wheat or rye, which become pasty when finely ground. Finely-ground mashes were compared with coarser mashes in Ohio and Utah experiments with laying hens.[107] The feed consumption and egg production were greater with the coarser mashes, and also in the Ohio trials the mortality was less. Very finely ground mash sometimes causes necrosis and malformation of the beak in chicks, because of feed adhering to the beak.[108]

1543. Wet mash.—Before modern, efficient rations were developed for poultry, the feeding of mash in wet form to laying hens was much more common than at present. Chiefly because of the saving in labor, the most common practice now is to supply dry mash at all times, and to feed wet mash in addition to laying hens only when it is necessary in order to stimulate feed consumption. (**1566**)

Feeding wet mash is a frequent practice in fattening poultry, as is pointed out in the next chapter. Wet mash is also sometimes used for ducks.

1544. Pellets; crumbles.—Pellets or crumbles are often used for poultry. (**91**) Crumbles, also called "granules" or "crackles," are made by breaking large pellets into smaller pieces by a machine. The cost of making crumbles is less than that of making the very small pellets needed for feeding chicks.

The chief advantage of pelleted or crumbled feed is that there is less wastage by feed being blown out of outdoor feeders, or being scratched or billed out of the feeders by the birds. This advantage is more or less offset by the higher cost of such feed.

Also, if the entire ration is pelleted, or a large part of it, the trouble from feather-picking or cannibalism is often much increased. To avoid this, it may be necessary to "debeak" the birds, or use other measures to prevent the trouble.

There is usually more advantage in pelleting a ration high in fiber than in the case of a high-energy ration. This is because the density is much increased, and the birds can eat more of the feed. For example, in a California trial with layers and in a Canadian experiment with broilers, pelleting rations consisting largely of barley, improved the results.[109]

Several experiments have been conducted to determine the value of pellets or crumbles for poultry.[110] The results of the trials with chicks, broilers, or growing pullets have differed.[111] In some cases the gains and the feed efficiency

have been slightly better on pellets or crumbles than on mash rations. However, in other tests the results from mash-feeding have been just as good.

For laying hens, only the mash for feeding with scratch grain may be pelleted, or the complete ration may be thus processed. Sometimes, hens fed rations of mash and grain or all-mash are given a mid-day supplemental feeding of pellets to stimulate feed consumption.

In the experiments with hens, there has usually been no difference, or only a very slight difference in egg production when pellets have been fed instead of mash.[112] The hens fed pellets may eat somewhat more feed and therefore maintain their weights better.

1545. Methods of feeding poultry.—Several different methods of feeding poultry are used successfully by practical poultrymen. The results secured with various methods of feeding laying hens and growing birds are discussed in the following chapter.

The most common method of feeding laying hens is to full-feed a laying mash in hoppers or troughs, and to feed in addition the desired amount of whole or cracked grain. This is either fed as scratch grain in the litter, or else a limited amount of grain is fed in troughs or hoppers. When it is considered desirable to stimulate feed consumption, a wet mash may also be hand-fed once a day.

In the all-mash method of feeding layers, the entire ration is full-fed as a mixture in hoppers or troughs. Another method is the "cafeteria method" in which mash and grain are self-fed separately. When fed by this method, hens eat much more grain than mash. Therefore, to balance the ration, it is necessary to use a mash which is considerably higher in protein and richer in vitamins than is needed in the other methods. As mentioned previously, sometimes the mash is fed in the form of pellets, or cubes.

Chicks are usually full-fed their entire ration in mash form for the first few weeks. Chick-size scratch grain is then often fed in addition. In the fattening of poultry, the entire ration is generally fed as a wet mixture. A wet mash is also often used for ducks.

1546. Pasture versus confinement or bare range.—With the development of modern complete rations that fully meet all the nutritive requirements, it has become possible to raise poultry to maturity in confinement and without any access to range or to fresh green feeds. Likewise, laying pullets and hens can be kept successfully in confinement during the winter season and even throughout the year. Finally, the extreme in confinement has been reached in the battery method, in which laying fowls are confined individually in batteries made up of small compartments.

Extensive experiments have been conducted to compare good pasture, or range, with confinement or bare range for growing pullets[113] or for laying hens.[114] These experiments have shown that pullets which have been raised on fresh, uncontaminated pasture are usually more thrifty than those raised in confinement. Therefore, even when the fowls are to be confined during egg production, they should, if possible, be raised on good pasture. Raising pullets in confinement is, however, preferable to rearing them on a range that is badly contaminated with parasites and diseases.

Numerous experiments have shown clearly that for farm flocks of small or moderate size, it is more economical to provide clean, uncontaminated pasture during the growing season than to keep the layers in confinement. In the southern states, pasture makes an even greater saving than in the North, because good forage can be readily furnished during all or most of the winter.

In large-scale poultry production it is often difficult or impossible to provide good pasture for the layers. It then becomes necessary to keep them confined and to use great care in feeding a ration that fully meets all their nutritive requirements.

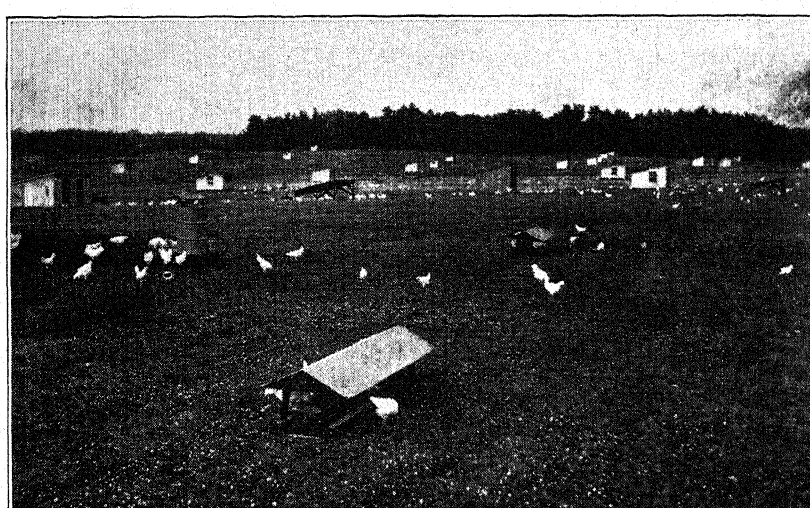
Good pasture for raising the pullets will usually save at least 5 to 10 per cent

of the total mash plus grain required, in comparison with feeding an efficient ration in confinement. There will be an even greater saving in cost, because there is a greater reduction in the amount of mash, which is more expensive, than in grain.

In addition, a much cheaper mash may be fed than is necessary without pasture. This is because good pasture is rich in protein and because pasture and direct sunlight combined fully meet all the vitamin needs. Information is given in the following chapter and in the example rations of Appendix Table VII concerning simple rations that are satisfactory for growing pullets and for laying hens which are on good pasture.

In most of the experiments with hens, the egg production has been higher on good pasture than in confinement or on bare range, and often the mortality has been less. In addition, there is a marked saving of feed by providing good pasture, and a cheaper mash, which contains less protein and vitamin supplements, may be used.

1547. Pastures for poultry.—Poultry will not eat much pasturage unless it is succulent and tender. To provide good pasture, the crop must therefore be kept growing actively over a long season. For this reason, the best poultry pasture is furnished by Ladino clover or other clovers, by alfalfa, by other legumes, or by such combinations as alfalfa and bromegrass or Ladino clover and grass. The various pasture crops are discussed in detail in Chapters XVI and XVIII. To stimulate new growth, the pasture should be mowed when necessary. (375)



Good Pasture Important for Raising Pullets

In addition to the saving of feed by the use of good pasture, pullets raised on fresh, uncontaminated pasture are usually more thrifty than those reared in confinement. (From Hurd, New York State College of Agriculture, Cornell University.)

Ladino clover or a combination of Ladino clover and grass is unexcelled for poultry pasture. (477) The crop is liked especially well by poultry, and it provides succulent pasturage over a long season.[115] In tests in the southern states, lespedeza, kudzu, and Dallis grass are among the pasture crops that have been very satisfactory.[116]

Kentucky bluegrass provides excellent pasturage in spring and fall, when it can be kept growing actively, but it often furnishes little forage in midsummer. In Kentucky experiments laying hens required about 20 per cent less concentrates on young bluegrass pasture in spring than was needed for hens in a dry

lot.[117] On the other hand, hens ate so little mature bluegrass that there was no appreciable saving of concentrates when hens were on such pasture.

1548. Clean, uncontaminated pasture essential.—To avoid serious infection with parasites and diseases, it is important to follow a careful pasture rotation system. The best plan is to provide pasture each year that has not been used by poultry the previous year, or even better, for two years. It is especially important to raise young stock on clean, uncontaminated pasture, from which the older poultry are fenced out.

It is a good plan to move the colony houses on pasture once a week to prevent killing out the pasture plants underneath. Another method is to move the feeders, waterers, and any range shelters, but not the colony houses.

An acre of good pasture should be sufficient for about 300 growing chickens or for 200 adult birds.

1549. Alfalfa meal or hay and substitutes.—The value of alfalfa meal or hay as a vitamin supplement for poultry has been discussed in Chapter XVI and also previously in this chapter. (**465, 1407, 1517, 1527, 1528**) Detailed information is given in Chapter XVI concerning the use of other kinds of legume hay in poultry rations.

Well-cured alfalfa hay and other legume hay not only supply carotene to meet the vitamin A requirements, but also help furnish B-complex vitamins and vitamins K and E, and one or more of the unidentified vitamins. In formula poultry mashes alfalfa meal is generally included as a vitamin supplement.

Although alfalfa or other legume hay is usually included in poultry rations in the form of meal, legume hay is sometimes supplied separately to farm flocks. In such cases it is generally fed as chopped hay, cut into one-half to one inch lengths and fed in wire baskets or containers.

Alfalfa or other legume chaff that accumulates where hay is pitched from a mow can be substituted for alfalfa meal. It may be fed dry, or it may be soaked and mixed with a wet mash.

Dehydrated young cereals or dehydrated vegetable wastes may be used as a substitute for alfalfa in poultry rations. (**586, 644**)

1550. Green feeds.—Before the use of alfalfa meal as a vitamin supplement became common, green feeds were often supplied poultry to furnish vitamins. When suitable pasture cannot be provided during the growing season, it may be beneficial to feed palatable green forage to laying hens and growing poultry, even when an efficient dry ration is used.

Green alfalfa, clover, or other legumes are excellent green feeds. Lawn clippings likewise rank high in vitamin content and palatability. Kale is used extensively for poultry in the Pacific Coast states. Rape is also often fed to poultry, but gives a dark color to the egg yolks. The waste parts of vegetables, such as cabbage leaves and carrot or beet tops, are good green feed for poultry. In the fall and winter, cabbage is often used as green feed. Cabbage is well liked by poultry, but it is not so rich in vitamins as green thin-leaved plants. Though cabbage is a rather expensive feed when grown for this purpose, the small and unmarketable heads make cheap feed for poultry.

Before modern poultry rations were developed, roots were used much more frequently than now for the winter feeding of poultry. Roots are well liked by poultry, but with the exception of carrots, they will not replace legume hay as a vitamin A supplement. Also, roots are much lower than legume hay in B-complex vitamins. In addition, they are usually an expensive source of nutrients in this country. (**627**)

When fresh green feed is fed to poultry, it is usually supplied at noon in such an amount as the birds will eat before night. A common allowance is 4 to 6 lbs. a day per 100 hens.[118] If hens are given all the palatable green feed that they will eat throughout the day, they may eat more than twice this amount. However, such a large allowance may make the egg yolks too deep in color to meet the demands of some markets.

1551. Silage.—Hay-crop silage, or so-called "grass silage," may be used instead of alfalfa meal as a vitamin supplement for poultry. (441) On the dry-matter basis, well-preserved hay-crop silage is even richer than good legume hay in carotene content. (437) Corn silage or sorghum silage is not generally fed to poultry, as it is too coarse and bulky.

When a ration for hens contains the usual amount of alfalfa meal, the egg production will not generally be raised by supplying hay-crop silage, but it does tend to increase the hatchability of the eggs.

As pointed out in Chapter XV, feeding more than 3 lbs. of hay-crop silage daily per 100 hens may produce dark-colored or greenish egg yolks. (441)

1552. Shelter.—To be healthy and profitable, poultry need quarters that are dry, well ventilated, well lighted, and free from drafts.[119] The poultry house need not be expensive, but should provide these essentials. Before building a poultry house, one should secure information from the state agricultural college or the local county agent concerning the type that is best adapted to the climatic conditions in the particular region.

On farms where poultry husbandry is an important enterprise, the laying hens are commonly kept in laying houses, and separate buildings are used for the young stock. These include brooder houses, movable colony houses, and range shelters. The simplest laying house is a one-story building with only one pen. For larger flocks laying houses with multiple pens are used. These are either long continuous one-story houses or multiple-story houses of two or more stories.

The laying house should be located on well-drained high ground, where the air movement will aid proper ventilation. Trees near the house will provide summer shade and also some protection from winter winds and storms. Unless the layers are to be kept in confinement, there should be ample range adjacent to the laying house.

In the house, about 3 square feet of floor space should be allowed for each hen of the smaller breeds, such as Leghorns, and 3¼ to 4 square feet per hen for the larger breeds. If the hens are confined in the laying house during the hot summer months, it is best to increase the allowance of floor space about one-half square foot per fowl. The normal decrease in size of flock from culling and mortality will often take care of this.

The house should be so arranged that it will be convenient to care for the poultry and with a minimum amount of labor. It is important that the house and all the fixtures be easy to disinfect. The fixtures—nests, perches, dropping boards, coops for broody hens, feed hoppers, etc.—should therefore be simple and removable. At least once a year and preferably twice a year, the house and all fixtures should be thoroughly disinfected.

1553. Air temperature and humidity.—California and Kansas experiments showed that an air temperature of about 65° F. is most favorable for high egg production.[120] A much higher or lower temperature tends to reduce the yield.

Poultry suffer from very hot weather.[121] (233) Feed consumption and egg production are much reduced. Also, the strength of the egg shells is lessened. High humidity increases the injurious effects of high air temperature.

In hot climates a method of cooling the birds is sometimes used. In California studies, with an air temperature of 90° F., mist-spraying laying hens for 30 seconds every 60 to 90 minutes was effective in reducing the body temperature.[122]

Shade in the pastures and good ventilation in the poultry houses are important in reducing the effect of hot weather.

1554. Litter.—The poultry house should be bedded with suitable litter, and this should be renewed when it becomes damp or filthy. Cut straw is used most often for litter. Other common kinds of litter are cut or shredded corn or sorghum stover, sawdust or wood shavings, ground corn cobs, peanut shells or hulls, cottonseed hulls, peat moss, and cane litter.

In Delaware studies various kinds of litter were given the following ranks for brooder houses: Peanut shells, first; followed in order by ground corn cobs, peat

moss, sugar cane litter, sawdust, shavings, cottonseed hulls, and corn stover.[123] Various kinds of mineral litter were less satisfactory.

Largely through investigations by Kennard, Chamberlin, and associates at the Ohio Station over several years, the use of "compost litter," or "built-up litter," has become common.[124] Other experiments have corroborated, in the main, their conclusions.[125] An important advantage of compost litter is that it makes it unnecessary to clean the house more than once a year, thus saving labor. Litter is also saved. Several broods of broilers, for example, can be raised on the same litter.

The compost litter is started in the fall with 4 to 6 inches of fresh litter fully covering the clean, dry floor. The litter is stirred up and leveled off about twice a week, and additional litter is added until the litter is 8 to 12 inches deep. It is important to stir the litter to prevent it from caking over the surface, and to mix the fresh droppings with the material below, which has been sanitized by bacterial action.

In cold, damp weather, it is beneficial to scatter hydrated lime, ground limestone, superphosphate, or gypsum over the surface before stirring it up. This keeps the litter drier and in better condition. Adding superphosphate also decreases the loss of nitrogen from the litter.

Any wet spots of the litter should be removed, as needed, and replaced by fresh material. Otherwise, none is removed until it may be necessary to take off some to prevent it becoming too deep for convenience.

Besides the saving of labor in using compost litter, there is a nutritional advantage. In the bacterial action that takes place, there is a considerable synthesis of B-complex vitamins, including vitamin B_{12}. Except when the ration has an ample supply of these vitamins, the growth of chicks or the egg production of hens may be appreciably increased by keeping them on compost litter. A disadvantage of compost litter is that sometimes there may be more trouble from coccidiosis or from round worms on such litter.[126] Also, inflammation of the cornea of the eye may occur in young chicks started on old compost litter, especially if it is damp. This is caused by ammonia in the litter.

1555. The egg.[127]—In several respects, an egg is similar to a grain, such as a kernel of corn. In each there is a germ, from which the new life develops, and each contains food for the nourishment of this germ. In the grain the stored food material is starch, fat, and protein, while in the egg the nutriment is stored in the form of protein and fat. While the grain must absorb much water for germination, the egg contains sufficient for its own development. Moreover, a much higher temperature is required for the hatching of the egg than for the germination of a seed.

An egg consists of five parts: (1) The shell; (2) the shell membranes; (3) the albumen; (4) the yolk; and (5) the germ. The *shell* makes up about 12 per cent of the weight of the entire egg. There are 2 layers of shell material, composed chiefly of calcium carbonate. On the outside of the shell is a thin protective coating, the cuticle, which protects the egg against bacterial invasion. This is similar in composition to the shell membranes inside the shell.

The *shell membranes* consist of 2 parchment-like layers, the inner one being the thinner. At the large end of the egg these layers separate, forming the air sac.

The *albumen*, or the white of the egg, which forms about 56 per cent of the weight, contains about 12 per cent dry matter, this being nearly all protein. When an egg is cooked, this albumen coagulates, or hardens.

The *yolk*, forming about 32 per cent of the egg, is enclosed in a delicate membrane which keeps it spherical in shape. The yolk contains an average of 48.7 per cent water, 16.6 per cent protein, 32.6 per cent fat, 1.0 per cent carbohydrates, and 1.1 per cent mineral matter.

The *germ* in the fresh-laid egg is a white speck about one-eighth of an inch in diameter on one side of the yolk.

The standard weight of hens' eggs is 2 ounces each, or 24 ounces to the dozen. Eggs weighing less than this sell at a discount on most markets. Those that weigh up to 26 ounces per dozen may sell at a premium, but extremely large eggs are not desired, as they are more apt to break when handled in ordinary containers.

QUESTIONS

1. Give an example of the increase in efficiency of production through modern rations and methods.
2. Tell how the digestive system of poultry differs from those of other farm animals.
3. Why are not rations for poultry commonly computed on the basis of digestible nutrients?
4. In what terms are feeding standards for poultry generally stated?
5. What percentages of protein are recommended in rations for: (a) Chicks up to 8 weeks of age; (b) chicks 8 to 18 weeks of age; (c) laying hens?
6. Discuss the importance of quality of protein for poultry.
7. Why should at least a small amount of a protein supplement of animal origin be included in a poultry ration, if possible?
8. Which amino acids may be deficient in practical, well-balanced rations for chicks?
9. Give an example of the way an amino-acid deficiency can be corrected.
10. Which pure amino acid is sometimes used as a supplement to practical rations?
11. Discuss the fat requirements of chickens.
12. What results have been secured by adding by-product animal fat to poultry rations?
13. Which minerals need special consideration in poultry rations?
14. Discuss the requirements of chickens for: (a) Calcium; (b) phosphorus; (c) salt; (d) manganese; (e) iodine.
15. Of what importance is grit for poultry?
16. Is it advantageous to add charcoal to poultry rations?
17. Discuss the requirements of poultry for vitamin A and carotene.
18. What is the effect of feed on the color of egg yolks and body tissues?
19. Discuss the vitamin D requirements of poultry, stating the form of vitamin D that is used efficiently by poultry.
20. Which of the B-complex vitamins is most important in feeding poultry? What supplements are used to supply this vitamin for poultry not on good pasture?
21. Discuss: (a) Niacin; (b) vitamin B_{12}; (c) other B-complex vitamins.
22. Is it generally beneficial to add yeast to poultry rations containing an ample supply of B-complex vitamins?
23. What disease is caused by an experimental ration deficient in vitamin E?
24. Discuss the importance of vitamin K for poultry.
25. Name 4 unidentified vitamins or factors that are needed by poultry and state a feed that supplies each of these.
26. Discuss the importance of net-energy values, or productive-energy values in poultry feeding.
27. What is meant by Calorie-protein ratio?
28. What advantages do metabolizable-energy values have over productive-energy values?
29. Discuss high-energy rations for: (a) Chicks and broilers; (b) layers.
30. Discuss antibiotic feed supplements in rations for: (a) Chicks and broilers; (b) hens or growing pullets.
31. What effects have generally been produced by adding an arsonic supplement to a ration for chicks or poults?
32. Have surfactant additions to poultry rations usually been beneficial?
33. How should water be supplied poultry?
34. Discuss the preparation of grain for poultry.
35. What is the chief advantage of pelleted feed for poultry? What is the disadvantage?
36. What different methods of feeding are used for laying hens?
37. Discuss the results from pasture versus confinement or bare range for poultry.
38. What are the best pastures for poultry in your region?
39. Why is it important to follow a careful pasture rotation system for poultry?
40. Discuss the use of alfalfa hay in poultry rations. What substitutes can be used instead of alfalfa?
41. To what extent are fresh green feeds used for poultry in your region?
42. What kind of silage may be useful for poultry?
43. Discuss the requirements of poultry for shelter.
44. What is the effect of very hot weather on chickens? How can these effects be reduced?

45. What kinds of litter are used for poultry in your region? Describe the method of using built-up litter.
46. Describe the structure of an egg.

CHAPTER XXXVII

FEEDING AND CARING FOR POULTRY

I. Feeding and Caring for Laying Hens

1556. Essentials in rations for laying hens.—In order to produce eggs economically, a high rate of egg production must be maintained in a flock of laying hens. To secure this, the hens must be fed a ration which is complete and well-balanced and which meets fully the nutritive requirements that have been discussed in the preceding chapter. It is also essential that the hens eat large quantities of feed. The ration must therefore be palatable and be fed in a manner that stimulates high feed consumption.

Detailed information has been given in the preceding chapter concerning the nutrient requirements of layers. Also, the ways have been explained by which these requirements can be fully met in practical rations. In Appendix Table VII several example rations are presented that are adapted to conditions in various regions.

1557. Grains for poultry.—All of the cereal grains can be used satisfactorily in rations for laying hens and for other poultry. Information about the use and relative value of the different grains for poultry is given in Chapters XX and XXI.

In most parts of the United States corn is the chief grain fed to poultry, and it gives excellent results when used in properly balanced rations. (**705**) Yellow corn aids in meeting the vitamin A requirements, and it also produces yellow color in egg yolks and body tissues. (**1518**) When other grains replace all or much of the yellow corn in a poultry ration, their lack of vitamin A value must be corrected by an ample supply of the vitamin from other sources.

Though oats are considerably lower than corn or wheat in net-energy value for poultry, they are desirable in poultry rations for certain special qualities. (**726**) Because of the oat hulls, including oats in poultry rations tends to prevent feather picking and cannibalism. The hulls also seem to provide a factor that improves growth and feather development in chicks and reduces mortality.

Heavy, plump oats should, if possible, be used for poultry, as light-weight oats have a low value for them. For use in a mash, oats should be ground fine enough to prevent the birds from picking out the kernels and leaving the hulls.

Wheat is liked the best of all the grains by poultry and is equal or slightly superior to corn in value per 100 lbs. (**738**) Though wheat is not at all essential in poultry rations, a limited amount is often fed, even when other grains are cheaper, because of the palatability of wheat and to furnish greater variety. If hens are fed, free-choice, all the wheat they will eat, and also mash, free-choice, they will usually eat a much greater amount of wheat than of mash. It may therefore be necessary to restrict the amount of wheat, in order to get them to eat enough of the mash to balance the ration properly.

Barley is a satisfactory substitute for corn or wheat in poultry rations. (**761**) It is somewhat less palatable than these grains to poultry, but they soon become accustomed to it. Because of the hulls, the feeding value of barley for poultry is appreciably less per pound than that of corn. For this reason, a large proportion of barley cannot be included in high-energy mashes.

The grain sorghums are widely used for poultry in the sorghum-belt, and are nearly equal to corn in value per pound. (**779**) Rice, emmer, hog millet, or buckwheat can also be used in poultry rations. (**783, 788–790**) Hominy feed is a

good substitute for corn in poultry rations. (708)

1558. Wheat by-products.—Wheat by-products are common ingredients of poultry mashes. (753) Because of the popularity of high-energy mashes, wheat bran is fed less than formerly. Instead, wheat middlings and wheat red dog, which are lower in fiber, are used.

The wheat by-products help furnish protein, and supply the vitamin or vitamins that are needed, in addition to manganese, for the prevention of perosis, or slipped tendon, in chicks. Rations containing these feeds also tend to produce more rapid growth and better feathering of growing chickens.

Because wheat bran and wheat standard middlings or brown shorts are considerably lower than grain in net-energy value for poultry, too large a percentage should not be included in poultry rations. The proportions of these feeds that are commonly used are indicated in the example rations in Appendix Table VII.

1559. Protein-rich supplements.—The protein requirements of poultry, both for amount and for quality of protein, have been discussed in the preceding chapter. As stated there, the best results are generally secured when the ration contains at least a small percentage of protein supplements of animal origin, such as dairy by-products, meat scrap, or fish meal. (1500) The advantage from animal-protein supplements is greater for poultry that are confined than for those on good pasture or range. This is due not only to the nutrients in the green forage they eat, but also to the insects and worms they secure, which help supplement their diet.

The desirable proportions of animal-protein supplements in rations for laying hens and for chicks are shown in the preceding chapter. (1501) If there is a shortage of animal-protein supplements, reasonably good egg production can be secured when such supplements are entirely replaced by soybean oil meal. It is then especially necessary to be careful to supply the proper amounts of calcium, phosphorus, and vitamins.

Information is given in Chapters XX to XXIII concerning the values and use of the many different protein supplements.

1560. Mineral, vitamin, and other supplements.—It has been emphasized in the preceding chapter that laying hens have particularly high requirements for calcium, because egg shells are composed almost entirely of this mineral. The most common method of supplying plenty of calcium for layers is to include 1.0 to 2.5 per cent of ground limestone or other calcium supplement in the mash, and also to let the hens have access at all times to oyster shell or limestone grit, fed separately. (1508)

The requirements of laying hens for phosphorus, manganese, iodine, and grit have been considered in the preceding chapter.

Unless laying hens are on first-rate pasture or are fed an abundance of fresh green feed, it is necessary to add vitamin A and riboflavin supplements to the ration. Also, unless the hens have sufficient exposure to sunlight which has not passed through window glass, a vitamin D supplement must be supplied.

Detailed information has been given in the previous chapter concerning the requirements of hens for other vitamins, including vitamin B_{12} and the unidentified vitamins or factors. Also, antibiotic supplements, arsonic supplements, surfactants, and hormones are there discussed.

1561. Amounts of feed required by laying hens.—The amount of feed required daily by hens depends on the rate of egg production, the size of the birds, their age, and the weather. Pullets require somewhat more feed than do mature hens for the same rate of egg production, as they are still growing. More feed is needed in cold weather than at other times.

Approximately the amounts of feed shown in the following table are needed daily by 100 laying hens at various rates of egg production.[1]

(A 30 per cent rate of egg production means that 30 eggs are laid daily per 100 hens.)

The estimates for light breeds are for such breeds as Leghorns, and those for heavy breeds, for such breeds as Rhode Island Reds, New Hampshires, or Plymouth Rocks.

Approximate daily amount of feed for 100 laying hens

Rate of egg production Per cent	Light breeds (av. wt. 4 lbs.) Lbs.	Heavy breeds (av. wt. 5½ lbs.) Lbs.
30	22	25
40	23	26
50	24	27
60	25	28
70	26	29
80	27	30

1562. Methods of feeding laying hens.—In almost all methods of feeding, laying hens are full-fed a mash which contains protein, mineral, and vitamin supplements. Sometimes all or part of the mash is fed in pelleted form. (**1544**)

Except in the all-mash method, the hens are fed grain separately, in addition. Generally, this grain is given in a limited or controlled amount, and fed either as scratch grain in the litter or in the proper amount daily in open hoppers or troughs.

Sometimes the cafeteria, or free-choice, method is used, in which both dry mash and grain are full-fed, separately in hoppers. The hens are allowed to eat as much of each as they wish. Another method is the use of an all-mash ration. In this method the proper proportion of grain (usually ground or cracked) is included in the mash, which is full-fed in hoppers.

Laying hens should not be changed quickly from one method of feeding to another, as this is apt to reduce feed consumption.

1563. Mash-and-scratch-grain method.—A common method of feeding laying hens is the mash-and-scratch-grain method. In this method a laying mash that contains 20 to 23 per cent of protein is full-fed dry in hoppers. In addition, a limited amount of scratch grain is fed by scattering it in the litter, so the birds will get exercise in scratching for it. The scratch grain is commonly a mixture of whole grains, though the corn is sometimes cracked coarsely.

In this method the aim is to have the hens eat approximately equal weights of grain and mash, so that their total ration will have the proper percentage of protein and also sufficient amounts of minerals and vitamins.

The mixture of grain is ordinarily more palatable to the fowls than the mash. Therefore, they will clean the grain up and then eat enough mash to satisfy their appetites. To build up the bodies of the birds or to increase the total feed consumption, the amount of grain should be increased, which automatically reduces the amount of mash eaten. To stimulate egg production, the amount of grain is reduced, so the fowls will eat more of the mash, containing the protein supplements. In cold weather, when there is a greater need for energy and when feed consumption is higher, the proportion of grain may be higher than when it is warmer. At no time should the hens eat more than 2 lbs. of grain for each pound of mash of the usual type.

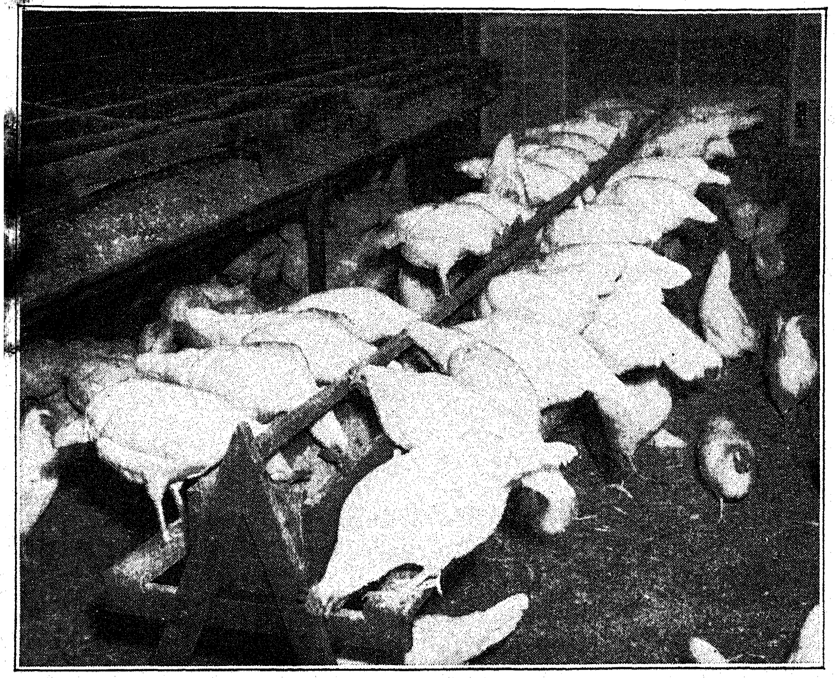
In order to get the hens to eat enough mash, only a light feeding of scratch grain is given in the morning (about one-fourth of the total daily amount). In the late afternoon, the hens are given all the scratch grain they will clean up, so they will go to roost with full crops.

The birds should be examined occasionally after they have gone to roost, to see whether they have had enough grain. At night it is better to feed a little more than will be eaten than not to feed enough. However, the morning feed must be light enough so that the grain will be entirely cleaned out of the litter before the afternoon feeding. During cold weather a small feeding of scratch grain is sometimes given at noon to keep the birds active.

Unless the hens are of an especially well-bred strain, the egg production is apt to be appreciably higher in this method than when grain is full-fed. Another important advantage of the scratch-grain method is that it keeps the litter

loose and dry. Feeding at least some grain in the litter is essential in using "built-up litter." (1554)

A disadvantage of this method is that it requires somewhat more skill and experience on the part of the poultryman than in the free-choice method or the all-mash method.



HENS EATING LAYING MASH FROM A FEED HOPPER

Note the guard above the hopper to prevent the hens from getting into it. (From Ogle, New York State College of Agriculture, Cornell University.)

1564. Mash with limited grain in hoppers.—Instead of feeding scratch grain in the litter, sometimes a limited amount of grain is fed in hoppers or troughs, in addition to the full-feeding of dry mash. The consumption of grain can be regulated in this method, just as in the scratch-grain method.

Generally, the grain is given separate from the mash, but sometimes it is distributed on top of the mash. If disease is present in the flock, it may spread less with this method than when scratch grain is fed in the litter.

When all of the grain is fed in troughs, the litter is apt to become packed down and badly soiled. To prevent this, some grain can be scattered in the litter in the morning.

1565. The free-choice, or cafeteria, method.—In the free-choice, or cafeteria, method, mash is full-fed at all times in open hoppers, or feeders. Grain is also full-fed, free-choice, in separate feeders. The hens are allowed to eat whatever proportion of mash and grain they desire. If more than one kind of grain is fed, the different kinds may be mixed together, or each kind may be supplied in separate feeders. A modification of this method is to feed some of the grain by hand in the litter, so that the birds will work over the litter and keep it loose and dry.

If corn or wheat is full-fed by this method, the hens are apt to eat much more grain than mash. Unless the mash is higher than usual in protein and also

in mineral and vitamin supplements, the ration will be too low in these nutrients. To aid in preventing this, a mash is often used which has 26 per cent or more of protein and also a higher content of mineral and vitamin supplements. Mashes that contain 26 to 30 per cent of protein are often called "supplements" and those containing 32 per cent or more of protein, "concentrates."

This method saves labor, and it is well suited for an inexperienced poultryman. It is better adapted to a flock which has an inherited capacity for high egg production than to a flock which is less well bred. It is also most successful when moist mash is fed in addition to the dry feed, or when the mash is supplemented with liquid or condensed skimmilk or buttermilk, or with pellets.

Several experiments have been conducted with laying hens to compare the free-choice feeding of grain and of mash with the feeding of a limited amount of grain and unlimited mash.[2] In some tests the results have been just as satisfactory with the free-choice method. However, in other trials the egg production has been lower and cannibalism and mortality have been greater with this method than when only a limited amount of grain was fed in addition to mash.

For example, the results have been decidedly better from limited grain feeding of pullets in tests during 7 years at the Ohio Station.[3] It was concluded from these experiments that rather than to full-feed grain separately, it was better to mix the whole grain and mash together in proper proportions, and then full-feed the mixture. This mixture may be fed once or twice daily in the amount that will be eaten before the next feeding period.

1566. Wet mash.—Since the development of modern poultry rations that fully meet the nutritive requirements, the feeding of mash in wet form to laying hens has become much less common than some years ago. Satisfactory feed consumption can generally be secured when a good dry mash is full-fed with grain in addition.

If the hens do not eat the desired amount of dry feed, it may stimulate consumption to feed some of the mash in wet form once or twice a day, supplying only as much as will be entirely cleaned up. However, feeding wet mash requires more labor. In 3 North Dakota experiments with laying pullets, there was no advantage from the regular feeding of wet mash in addition to dry mash and grain.[4]

Often, supplemental wet mash is fed to layers in hot summer weather, in order to keep up feed consumption and to aid in keeping the hens from going into a molt. In 3 Oregon trials with yearling hens, such supplemental feeding of wet mash delayed molting and increased the net returns.[5]

1567. All-mash method.—In the all-mash method of feeding laying hens, a single mash mixture is used, which includes all the grain as well as the supplemental feeds. In addition, the hens may be given free access to a calcium supplement and grit, or the entire amount of calcium supplement needed may be included in the mash.

This method has become much more common in recent years with the use of automatic feeding equipment in large scale poultry enterprises, and with the extensive adoption of laying batteries in some areas. It is used less frequently for layers housed in floor pens.

Except where automatic feeders are used, the mash is fed dry in hoppers, to which the hens have access at all times. The grain is usually all ground, which slightly increases the cost. The mixture should not be too fine, or it will be less palatable. Sometimes whole grain, such as oats, is included in the mash.

An all-mash ration must include the proper proportion of protein and vitamin supplements. Usually such a ration has about half as much of these supplements as a mash for feeding with scratch grain.

If there is considerable trouble from disease in the flock, there may be an advantage in this method, because the feed is not contaminated by the litter, as may occur in the feeding of scratch grain. Also, the color of the egg yolks

can be controlled more uniformly with the all-mash method, because all of the hens must eat the same mixture of feeds.

The all-mash method gives very satisfactory egg production when a high-energy mash is used. If a bulkier mash is fed, containing more fiber, it is difficult to maintain high egg production and keep up the body weights of the birds, especially in cold weather. In recent New York experiments, high egg production and satisfactory maintenance of body weight were secured on a high-energy, all-mash ration in winter, without supplemental feeding of pellets.[6]

In some experiments comparing the all-mash method with feeding whole grain in addition to mash, the results have been just as satisfactory from the all-mash rations, especially with high-energy mashes.[7] In tests with mashes having less productive energy, the egg production has often been appreciably lower with the all-mash method, even when pellets were fed in addition.

A disadvantage of an all-mash ration is that the litter is apt to become packed down and wet. More frequent cleaning of the pens is therefore often needed. Also, there is an added cost for grinding all the grain.

When an all-mash ration is fed in hoppers, fresh feed should be added daily, and the feed should preferably be stirred up several times a day.

1568. Use of artificial light.—Many poultrymen use electric lights to provide additional light in the laying house during the fall and winter, in order to lengthen the hours of light and thus secure more eggs when the price is usually highest. Numerous experiments have been conducted to determine the effects of using artificial light for laying hens.[8]

The experiments have shown that in fall and winter, when the days are short, the egg production is appreciably increased by lengthening the time when it is light. However, the annual egg production is generally not increased, because the hens do not lay so many eggs during the following spring and summer.

It was originally believed that the increase in production thus secured was due to the lengthening of the time during which the hens were able to feed. Investigations have shown, however, that the additional light has a stimulating effect on the pituitary gland and steps up its hormone secretion.[9] (**54**) This increases egg production, even when the hens are not allowed to eat additional feed.

Generally, lights are used for a sufficient period each day to provide, together with the daylight, about 13 to 14 hours of light. In the most common method, the lights are turned on by an automatic clock device some hours before daybreak, and then turned off when daylight comes. This method is about as effective as any. Where electricity is cheap, lights are sometimes used all night.

A 40-watt bulb gives enough light for a pen of 50 to 100 hens. The light should be placed in the center of the pen, over the feeders and waterer. It should have a broad reflector to throw the light toward the floor.

When lights are used, the feeding schedule should be so arranged that the birds will have plenty of feed during the entire time that it is light. For example, when lights are used early in the morning, grain for the morning feeding should be scattered in the litter or be put in the feed hoppers in the evening after the birds have gone to roost. It is important to regulate the feeding so that egg production will not be stimulated so much that the hens run down in condition.

1569. Points in feeding and caring for hens.—The advantages of providing good pasture for poultry have been emphasized in the previous chapter. (**1546**) Wherever it is possible, suitable uncontaminated pasture should be provided for the laying flock. This will not only save feed, but will also make possible the use of a cheaper mash.

The combination of good pasture and exposure to sunlight will largely take care of the vitamin requirements. Also, legume pasture or even young grass pasture helps meet the protein requirements. Therefore, less protein and

vitamin supplements are needed in a mash for hens on good pasture. Furthermore, when hens have free range on first-rate pasture, no protein supplements of animal origin are necessary. The protein supplements can then be entirely soybean oil meal combined with other supplements of plant origin.

When range is provided for the layers during the winter season, it is advisable during wet or rainy weather to keep the flock in the house until one o'clock in the afternoon, in order to reduce the number of dirty eggs. The eggs should be gathered before the fowls are turned out.

Plenty of fresh water should always be provided laying hens. (**1541**) As stated in the preceding chapter, grit should also be supplied. (**1514**)

When laying hens are confined in laying cages or batteries, instead of being housed in the usual manner, special care is necessary to feed a ration that completely meets their nutritive requirements. The all-mash method of feeding is generally used. Fresh feed should be supplied each day, and feeders and water troughs must be kept clean.

In a flock on a general farm it is generally best to use pullets instead of mature hens for egg production. On the other hand, the use of mature hens is highly desirable in constructive breeding.

Pullets generally produce more eggs in a year and more eggs in the fall than do mature hens, but the eggs of pullets are smaller. If not enough good pullets are raised to replace the entire flock, good production can, however, be secured from carefully culled mature hens. In Michigan tests, the egg production per bird and the cost per dozen eggs were about the same for pullets and for selected mature hens.[10]

To save feed and reduce the cost of egg production, it is important to cull the flock carefully not later than March 1. By examining each bird, an experienced poultryman can cull out the non-layers, as well as any birds which are diseased or injured.

1570. Costs in egg production.—Feed is by far the largest item of expense in egg production. The cost of feed will generally be slightly more than one-half of the total gross cost. Man labor is next in importance, forming about one-fourth of the total expense. To the cost of feed and man labor must be added the other expenses, including the charge for the use of buildings, land, and equipment, the cost of chicks or hatching eggs purchased, expense for tractor or horse labor and for use of automobile and truck, interest on capital used in the enterprise, and miscellaneous expenses.

The cost of producing eggs will, of course, vary widely, depending chiefly on the prices of feeds and the cost of labor. The cost per dozen eggs will be much less when the annual egg production per hen is high than in a flock with poor egg production. Labor-saving equipment and efficiency in the use of labor are important in reducing the cost. Where egg production is the chief source of income or an important source, enough hens must be kept to utilize equipment and labor efficiently.

The most extensive studies of the costs of egg production in commercial flocks have been by the N.Y. (Cornell) Station.[11] For many years costs have been determined on a large number of commercial poultry farms in the state. During this time the average annual egg production per hen has increased steadily, because of improved nutrition, breeding and management.

For example, in 1926 the average was only 126 eggs per hen on the farms studied. By 1935, the average yield had increased to 150 eggs a year, by 1945 to 172 eggs, and in 1952 to 188 eggs.

In 1952, 113 lbs. of feed were consumed per hen a year, and 1.7 hours of labor were needed. Per dozen eggs, 7.2 lbs. of feed and 0.11 hour of labor were required.

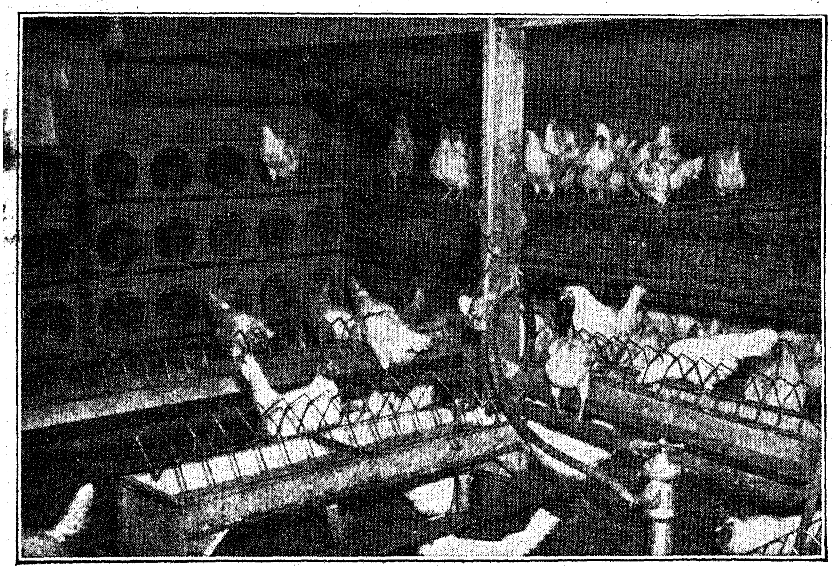
The cost of feed was 60.4 per cent of the total cost; labor, 17.0 per cent; flock depreciation, 11.3 per cent; and other costs, 11.3 per cent.

From these studies, a formula was developed for estimating the cost of

producing market eggs at any time in this area.[12] According to this formula, the average cost per dozen eggs is estimated as follows: Add together the cost of 7.2 lbs. of feed, 0.11 hour of labor, and 3.5 per cent of the farm value per bird (this item to cover flock replacements and depreciation). Increase this total by 13 per cent to cover the other costs.

the net returns per hen and per hour of labor in this study were decidedly greater from the Leghorn flocks than from the flocks of heavy breeds.

The cost of raising pullets for replacement was the same with the heavy breeds when straight-run chicks of both sexes were used, as it was in Leghorn flocks with sexed female chicks.[14] However, when sexed female heavy-breed



A Well-Arranged Laying House

The equipment is arranged so that only the minimum amount of labor is needed in feeding and caring for the flock. (From Ogle, New York State College of Agriculture, Cornell University.)

chicks were reared, the cost per pullet was 9 per cent higher. The difference was due to good returns from the male chicks, sold as broilers, from the straight-run heavy-breed chicks.

In studies for 1950–51, Leghorn flocks producing market eggs averaged 1,099 layers per flock, yielded 203 eggs per hen, and required 6.8 lbs. of feed per dozen eggs.[13] Flocks of heavy breeds averaged 820 layers per flock, yielded 192 eggs per hen, and consumed 7.6 lbs. of feed per dozen eggs.

In the Leghorn flocks, the hens disposed of for meat averaged 4.7 lbs. in live weight and brought an average of $1.07. In the heavy-breed flocks, the hens sold averaged 6.5 lbs. and brought $1.98.

Considering all costs and the returns for both eggs and for birds sold,

II. Raising Chickens

1571. Selection of breeding stock.—Just as is the case with other livestock, good returns cannot be expected from poultry unless one has a flock of birds that have high productive capacities and strong constitutions. The feeding of an ideal ration and the best of care will not compensate for a lack of inherited productive capacity.

It is outside the scope of this volume to discuss the principles and methods of livestock breeding and selection. Only certain summary statements can therefore be made concerning the selection of poultry for breeding. The fowls should be carefully selected for the following characteristics:

The strain should produce strong, vigorous chicks that make rapid growth and mature early. The pullets should begin to lay in the fall and continue a high rate of production steadily through the winter, without any "winter pause." The eggs should be of good size, shape, and color and of high hatchability. The strain should be resistant to disease, should not have a tendency toward cannibalism, and should be long lived.

It will pay every poultryman who saves his own eggs for hatching to follow some method of banding throughout the year, in order to identify the hens that have these desirable characteristics. He will then be able to separate the best hens in the flock and to save eggs for hatching only from them. A close observer can usually distinguish between hens that are layers and those that are not. However, the breeder who wishes to build up a high-producing flock should not rely on observation alone, but he should install trap nests and find out not only which hens are laying, but also how many eggs each lays.

Yearlings or older hens are much preferable to pullets for the production of eggs for hatching. They have proved their ability to live through the first year as layers, and have been retained for another year because they were good producers. Chicks from hens' eggs are generally larger than those from pullets' eggs. Also, in Ohio tests, the mortality during the first year of pullet layers hatched from yearling hens' eggs was considerably less than of pullets hatched from eggs produced by pullets.[15]

When chicks are purchased from a hatchery, one should be sure that they come from healthy, vigorous birds that have been bred for high production.

1572. Feeding and management of breeding hens.—To secure eggs of high hatchability which will produce strong vigorous chicks, the breeding hens must be fed a complete, well-balanced ration.[16] Any deficiency, no matter whether of protein, minerals, or vitamins, is apt to lower the hatchability seriously or to result in weak and unthrifty chicks. For the production of high-quality hatching eggs, the breeding flock must not only be fed properly during the hatching season, but also for some time previously.

The hatchability is generally better when the hens are fed a ration containing a fair proportion of protein supplements of animal origin, such as milk by-products, meat scrap, and fish meal, than when it contains only plant-protein supplements. It is stated in the preceding chapter that for breeding hens the mash to be fed with grain should contain 7 to 10 per cent of animal-protein supplements. (1501) For layers, not producing hatching eggs, 5 to 7 per cent of animal-protein supplements is satisfactory in a mash to be fed with grain.

In the production of eggs for hatching, care must be taken to meet the mineral needs. Experiments have shown that a lack of calcium decreases hatchability. Also, as shown in the preceding chapter, 15 milligrams of manganese per pound of feed is needed in a ration for breeding hens to secure good hatchability. (1511)

A deficiency of vitamins is probably the factor that most frequently lowers hatchability. An ample supply of vitamin A and of vitamin D is essential. However, no greater allowances of these vitamins are considered necessary for breeding hens than for hens producing market eggs. (1498) On the other hand, larger amounts of riboflavin, pantothenic acid, and folic acid are advised for breeding hens.

Sunlight which has not passed through window glass provides vitamin D. In addition, certain experiments indicate that even when there is plenty of vitamin D in the ration, the hatchability is improved when hens are exposed to direct sunlight.

Supplying breeding hens with fresh green feed tends to increase hatchability.

When this is not available, it is important to include in the ration a sufficient amount of alfalfa hay, alfalfa leaf meal, or a satisfactory substitute.

To secure high hatchability, the hens must be kept in good physical condition. Before they can produce satisfactory eggs for hatching, yearling hens need a rest period after heavy production in their pullet year. During this rest period, they molt, grow a new set of feathers, regain any lost weight, and build up stores of nutrients in their bodies.

About 3 months should be allowed for this rest period and for getting the hens back into full production. The hatchability is generally not satisfactory until hens have reached a good level of laying, and it is usually higher for high producers than for poor layers.

1573. Saving eggs for hatching.—To insure high fertility of eggs for hatching, a sufficient number of well-bred, vigorous roosters should be placed with the hens. With vigorous males, one is generally provided for each 15 to 20 hens of the egg breeds, and for each 10 to 15 hens of the general-purpose breeds.

Although some fertile eggs may be produced about 24 hours after males have been placed with the hens, a satisfactory level of fertility is not likely to be reached until after about a week, and for maximum fertility, 10 days may be needed.

Medium-size eggs are best for hatching.[17] The hatchability is usually lower from very small or from extremely large eggs.

Care must be taken to keep eggs clean that are to be hatched. Eggs may be held, without any apparent loss of hatchability, for a week or even somewhat longer at a temperature of 50 to 55° F. before they are incubated. When eggs are thus held, it is a good plan to stand them on the small end in ordinary egg case fillers. If eggs for hatching are held for more than a week or 10 days, they should be turned once a day. A simple way to turn eggs sufficiently in an ordinary egg case is to tilt the case daily by placing a block under one end of the case.

1574. Best time for hatching chicks.—In order to secure the best returns from egg production, it is important that the chicks be hatched early enough in the spring so that the pullets will lay well in fall and early winter, when egg prices are ordinarily highest. Too often, at this time the pullets in farm flocks have not begun to lay, and the old hens are not laying, but are molting.

Pullets of the lighter breeds, such as Leghorns, should come into laying when 5 to 6 months old, and those of the heavier breeds, when 5½ to 6½ months old.

Another advantage of early-hatched chicks is that those which are hatched late generally do not do so well as early chicks, because of the hot weather in summer. A third advantage of early-hatched chicks is that the males may be sold as broilers early in the season when prices are usually slightly higher than later.

In commercial poultry plants, some pullets are often reared at other seasons of the year. This makes it possible to replace birds that die or are culled out; to secure more uniform egg production throughout the year; to make more efficient use of labor and brooding equipment; and to secure a greater number of offspring from the fowls of outstanding merit.

In a New York survey of the results on large-scale poultry farms, it was found that fall-hatched pullets, put into the laying house in April, produced a greater net return than spring-hatched pullets.[18] However, where the winter climate is cold, unless excellent facilities are provided for raising fall-hatched pullets, they are apt to be much less satisfactory than those hatched in the spring.

1575. Hatching the chicks.—In all intensive poultry districts of the United States, incubators have replaced hens for hatching chicks. However, in some sections of the country a considerable percentage of the chicks are still hatched by hens.

Modern incubators are easy to operate, if the directions furnished with the machine are carefully followed. After each

hatch, the incubator should be thoroughly cleaned and disinfected to prevent the spread of disease. Before putting in the eggs, the temperature should be checked for at least a day to see that the regulator is adjusted.

The eggs are tested during incubation, and all infertile eggs and those with dead embryos are removed. The hatch should be completed by the end of the twenty-first day of incubation. None of the chicks should be taken out of the incubator until they have dried off and are "fluffed out." When they are removed, they should be placed where they will not be chilled.

At elevations of 5,000 feet and above, the hatchability of eggs is commonly much lower than at low elevations. In recent experiments it has been found that this is due to the reduced oxygen content of the air at the high elevations.[19] By increasing the oxygen in the incubator air approximately to the percentage at sea level and also controlling the carbon dioxide content, normal hatchability is secured.

1576. Hatching eggs with hens.—When eggs are hatched with hens, clean nests should be prepared in a dark, cool, well-ventilated, and quiet place. The nest should be about 16 inches square. It should be of such depth that the chicks cannot fall out at hatching time, while it is shallow enough so that the hen will not have to jump down into the nest. It is best to place the nest box on the floor so the hen can get into it readily.

Oat straw is the best nesting material, and wheat straw, hay, or leaves are preferable to shavings. The straw or hay should be cut into 6-inch lengths if it is too long. It is well to place a hollowed-out sod or some soil in the bottom of the box, to provide moisture. The straw should be put over this and rounded into a nest shape, with the nest a trifle deeper in the center than it is at the sides, to keep the eggs from rolling out.

The hens should be examined carefully for lice. If any are found, the hens should be dusted thoroughly with sodium fluoride powder before setting them, and again after 10 days. This will rid the hens of lice and prevent the chicks becoming infested.

After placing 2 or 3 nest eggs in each nest, the hens are moved to the nest just at dark. The next day they should be taken off and given feed and water. If they do not return to the nests in 20 to 30 minutes, they must be driven back or caught and confined to the nest. As soon as the hens settle down, they should be given the eggs. Until hatching starts, the hens should be taken off or allowed to come off daily.

The hens should be fed whole or cracked grains, such as corn or wheat, and occasionally some green feed. The feed should be kept near, so that the hens will not have to leave their nests for a long time to get feed. Grit and fresh water should be placed where the hens can get them when they come off the nests daily.

1577. Artificial brooding.—When a large number of chicks are raised, brooders are generally used instead of rearing the chicks with hens.[20] By this method the chicks can be raised at any desired time, and much labor is saved. Brooders are of three types—portable brooders, continuous brooder houses, and battery brooders. Except in very large poultry plants, the portable brooders are most common. These can be moved to fresh, uncontaminated ground each year, so that the chicks can be raised under the most favorable conditions. Brooders are usually heated by coal, oil, or electricity.

Before the chicks are put into the brooder, the house, the hover, and all utensils should be carefully cleaned and disinfected, if the brooder has been used before. One should be sure that the house is free of mites.

Chicks are generally left in the incubator 24 to 36 hours after hatching, before they are removed to the brooder. This should have been in operation for 2 to 4 days before the chicks are placed in it, in order to see that the temperature is regulated properly.

The first day, the brooder is kept at a temperature of 94° or 95° F. The

temperature may then be lowered uniformly about 0.8° F. a day until it reaches 70° F.

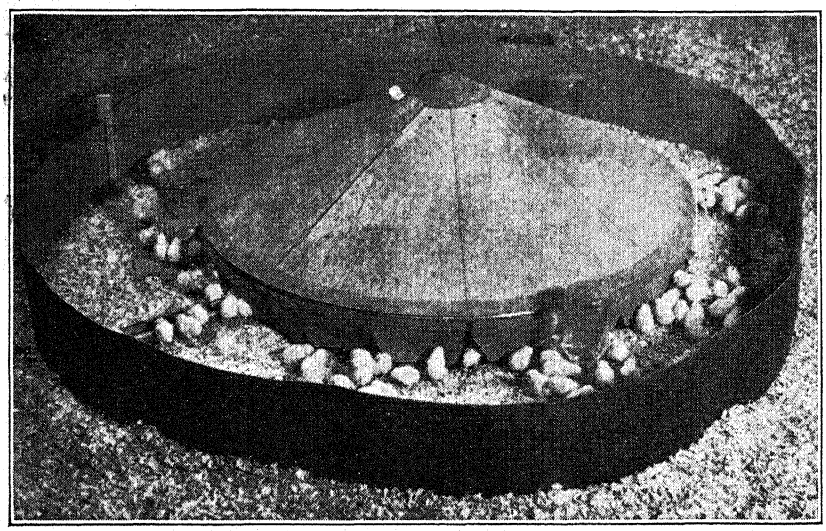
The heat is usually discontinued when the chicks are well feathered. Early in the spring it may be needed for 8 to 12 weeks in the northern states, and for only 4 to 6 weeks later in the season.

The chicks should have chick starter and water or milk available as soon as they are placed in the brooder house. To keep them from straying away from the hover to the corners of the house, a guard of one-half inch wire mesh should be placed around the hover and 2 or 3 feet from its edge. This may be covered with burlap sacking at first to protect the chicks against cold floor drafts. The space inside is gradually enlarged, and the guard is usually removed when the chicks are about a week old. Pieces of wire mesh or else boards should be placed across the corners of the house to prevent the chicks from crowding into the corners and some being smothered by the piling up.

The floor of the brooder under and around the hover should be covered with fine litter, such as cut straw, shavings, cut alfalfa or clover hay, peat moss, or finely ground corn cobs. Sometimes sand is used. Combustible litter must be kept away from the stoves. An advantage of using cut alfalfa or clover hay for the first 3 or 4 days is that it is partly digestible and is not apt to cause impaction if the chicks eat it.

For disease control, it is important to keep the litter dry. A layer of 2 to 3 inches of litter is enough at first, but by the time the chicks are 8 to 10 weeks old, the litter should be 4 or 5 inches deep. The litter should be stirred up daily to keep it dry. Any wet litter around the drinking fountain should be replaced with fresh material or with dry litter from other parts of the floor.

In suitable weather at 5 to 6 days of age, when the chicks have learned where to go to get warm, they may be allowed to run out into a small outdoor yard. A sloping runway should be made by piling dirt in front of the chick door, so the chicks can readily get in and out of the brooder house. After the chicks learn how to find their way back to the



A Simple Electric Brooder

The chicks are in a clean house with clean litter. Note the chick guard around the hover, the waterer in the right foreground, and the feeders for the chick starter. (From Ogle, New York State College of Agriculture, Cornell University.)

house, the enclosure can be removed and the chicks allowed to range at will.

Low roosts should be placed in the brooder house when the chicks are 3 to 4 weeks old, so that they will learn to roost at an early age. This will prevent them from crowding together on the floor at night, and becoming overheated or even smothered. In hot weather good ventilation of the house is essential.

It is best to separate the males which are to be sold as broilers by 8 weeks of age, if they can be identified. They can then be fed a broiler mash until they are sold, while the pullets are fed a growing mash and otherwise managed for the production of layers.

1578. Brooding chicks with hens.—In rearing chicks with hens, the essentials are few. A quiet, motherly hen should be placed in a portable coop which will allow the chicks free range but in which the hen can be confined if desired. The coop should protect the hen and the chicks from the weather and from enemies, and should be located on a grassy, shady range. Early in the season, it is usually best to have board bottoms in the coop, but later in the season and in dry weather this is not necessary. When board bottoms are used, they should be covered with cut litter or sand, which should be changed at least once a week. When no bottoms are used, the coop should be moved to a fresh spot at least every other day. This will prevent killing the grass and will fertilize a larger area.

As soon as the chicks are 10 days old, the mother hen may be turned loose toward night and allowed to run with the brood. She can be given her liberty during the day when the chicks become accustomed to following her. On most farms, the hens with their broods can be moved to some field where they can find a large part of their living.

As soon as the chicks are old enough to look out for themselves, which will be in 4 to 6 weeks in warm weather, the hen may be removed. The chicks will do better by themselves, and the hen will start laying sooner if separated from the chicks.

When the chicks are hatched in incubators or are purchased from hatcheries, broody hens are sometimes used to raise the chicks. They are each given a couple of chicks to test them out just at dark, and early the next morning the best mothers are selected and each given from 12 to 20 chicks.

1579. Nutrient requirements of chicks.—Because of the discoveries made concerning the nutrient requirements of poultry, it is now possible to raise thrifty chicks at any time of the year, and even in confinement and without any fresh green feed. The requirements of chicks and also of older fowls for the various nutrients have been considered in detail in the preceding chapter.

It will be noted that the committee of the National Research Council recommends that chick starters for feeding chicks during the first 8 weeks should contain 20 per cent protein. (**1498**) For chicks from 8 to 18 weeks of age, rations containing 16 per cent protein are advised.

It has been pointed out previously that chickens fed a high-energy ration need a slightly higher percentage of protein than do those fed rations containing more fiber. (**1499**) Consequently, the rate of gain may be a little more rapid on a high-energy ration, especially for chicks of the heavier breeds, if the ration has at least 21 per cent of protein for the first 6 to 8 weeks, and then at least 17 per cent.

Mashes for chicks to 8 weeks of age should preferably have not less than 5 to 7 per cent of protein supplements of animal origin. (**1501**) Mashes to be fed with scratch grain to growing chickens after 8 weeks should have at least 5 to 7 per cent of animal-protein supplements.

Chicks and growing chickens need a decidedly smaller percentage of calcium in their rations than do laying hens. As stated previously, 1.0 per cent of calcium is sufficient. (**1508**)

Rations for chicks and growing chickens should have at least 0.6 per cent phosphorus, and at least 0.45 per cent should be inorganic phosphorus. (**1509**)

If liberal amounts of animal-protein supplements are included in rations for chicks, there may be an ample supply of phosphorus. On the other hand, it will commonly be necessary to include a calcium supplement in the ration. It is important to include one-quarter pound of manganese sulfate in each ton of chick mash, to insure an adequate amount of manganese. (1511)

It will be noted in the preceding chapter that chicks require less vitamin A and vitamin D per pound of feed than do laying hens. (1517, 1519) On the other hand, chicks up to 8 weeks of age need a larger allowance of riboflavin per pound of feed than hens require. (1520)

The importance of vitamin B_{12}, of the unidentified vitamins or factors, and of other vitamins for chicks has been discussed in detail in the preceding chapter. (1523–1529)

Proper growth of chicks cannot be expected unless they are fed a ration that amply meets their requirements. Often farmers who feed good chick starters during the first few weeks, substitute only farm grains for the more expensive chick mash when the chicks are 2 to 4 weeks old.

A North Dakota test shows the poor results produced by this practice.[21] Chicks fed only grain after they were 3 weeks old averaged only 0.82 lb. in weight at 11 weeks of age, while others fed a well-balanced mash averaged 1.95 lbs. Both groups were then fed a balanced ration, but at 22 weeks of age the pullets which had been fed only grain for a time were 0.7 lb. lighter than those fed properly at all times. Also, three-fourths of the pullets fed inadequately for a time had crooked breast bones, and their bones were weak.

1580. Feeding the chicks.—Baby chicks should be given feed and water as soon as they are placed in the brooder. Some years ago it was a common practice to withhold feed from chicks for 60 to 72 hours after hatching. During this time they secure nourishment from the remainder of the yolk, which is drawn into the body just before hatching.

While strong chicks can usually go without feed for this length of time without injury, it is difficult for some to stand the strain. Investigations have shown that it is decidedly preferable to supply feed as soon as the chicks are put in the brooder. Otherwise, they are apt to eat litter and droppings. The ability of chicks to live for a few days upon the remainder of yolk within their bodies makes it possible to ship baby chicks from hatcheries for a considerable distance.

The feed for baby chicks should be easily accessible, and there should be plenty of feeding space, so that they will learn to eat readily. About 1 inch of feeder space should be allowed per chick to 2 weeks of age, and 2 inches after that.

For the first 2 or 3 days, some of the chick mash, or chick starter, should be fed twice a day in small trough feeders about 1 inch deep and 2 or 3 inches wide. Sometimes chicks are given their first feeds on newspaper or cardboard. However, there is then danger of the droppings becoming mixed with the feed, which may spread disease. When the chicks have learned to eat, larger trough feeders should be used, with guards to prevent the chicks getting into the feed. Such feeders lessen feed wastage and keep the droppings out.

As soon as the chicks have learned to eat from the feeders, both the feeders and the fountains should be placed on platforms which are 6 inches high and covered with wire or slats. This prevents the litter from being scratched into the feeders or fountains, and the chicks do not come in contact with the wet spots where water may be spilled from the fountains.

After the chicks are 8 or 10 weeks old, larger feeders are used. If the chicks have outside range, most of the feeding may be done in protected outdoor feeders. Even then, it is well to have one feeder in each brooder house for rainy days.

For the first 4 to 8 weeks, chicks

are generally fed only chick starter, or chick mash. After this, a common method is to feed chick-size grain in addition to mash. However, many poultrymen continue the all-mash method during the entire growing period. All-mash rations are generally used in broiler production. Sometimes the mash for chicks is fed in the form of pellets or crumbles. (**1544**)

If the rations are equally well balanced, the results are about equal from all-mash rations for raising chicks, and from feeding grain in addition to mash, after the chicks are 4 to 8 weeks old.[22] As stated previously, chick starter mashes for the first 8 weeks should have not less than 20 per cent protein. After about 8 weeks of age, grower mashes for all-mash feeding should have at least 16 per cent protein.

Mashes for feeding with grain must be higher in protein and in mineral and vitamin supplements than a mash used in the all-mash method.

When grain is fed in addition to mash, chick-size grit should be supplied. (**1514**) In all-mash feeding, the entire amount of calcium supplement needed is included in the mash, and no grit is necessary.

Occasionally, there is trouble from diarrhea in chicks during the first week, which causes the condition known as "pasting up." This seems to be most apt to occur on a mash high in soybean oil meal. Experiments have shown that the trouble can usually be prevented by feeding only chick-size scratch grain, or else grain in addition to mash, during the first 2 or 3 days, instead of mash alone.[23]

Liquid skimmilk or buttermilk is excellent for chicks, and may be given as the only drink for the first 3 to 4 weeks. At 4 weeks of age pullets should get water in addition, so as to reduce the protein content of the ration and prevent too rapid development. Cockerels intended for broilers may get only milk to drink until they are sold.

Fresh, uncontaminated range should be provided for the chicks as soon as the weather is suitable. While chickens can be raised in confinement when a complete ration is fed, the pullets will commonly be much more thrifty and also more productive if they have been raised on good range. Raising chickens in confinement is preferable, however, to allowing them to become diseased and infected with parasites by ranging over badly contaminated ground. If fresh range cannot be provided for chicks, it is the best plan to let them have access during the day to a sun porch floored with wire netting.

Several example rations for chicks are given in Appendix Table VII which are adapted to various sections of the country. Statements are also there made concerning the ways in which these rations may be changed to adapt them to local conditions.

1581. Raising pullets and cockerels.—Wherever possible, the pullets should be reared in a movable colony house on clean, uncontaminated pasture. They should be kept entirely separate from the older chickens, so as to avoid the spread of disease and parasites.

The pullets must be fed liberally, so that they will make good growth and be ready to start laying in the fall. The most common method of feeding is to supply a suitable mash in hoppers and also a mixture of grain. Sometimes the all-mash method of feeding is used. Water and grit should be accessible at all times, and oyster shell or some other calcium supplement should be provided separately, if a sufficient amount is not included in the mash.

In a recent Wisconsin experiment pullets were raised to 20 weeks of age on an all-mash, corn and vegetable-protein ration with a vitamin B_{12} supplement.[24] Other groups received rations containing also an antibiotic supplement and, in addition, fish solubles or fish meal to supply unidentified growth factors. After 20 weeks all groups were fed a complete, well-fortified laying ration.

The pullets raised on the complete rations were heavier at 20 weeks, and slightly heavier at a year of age. There were no appreciable differences in the amount of feed required per pound of

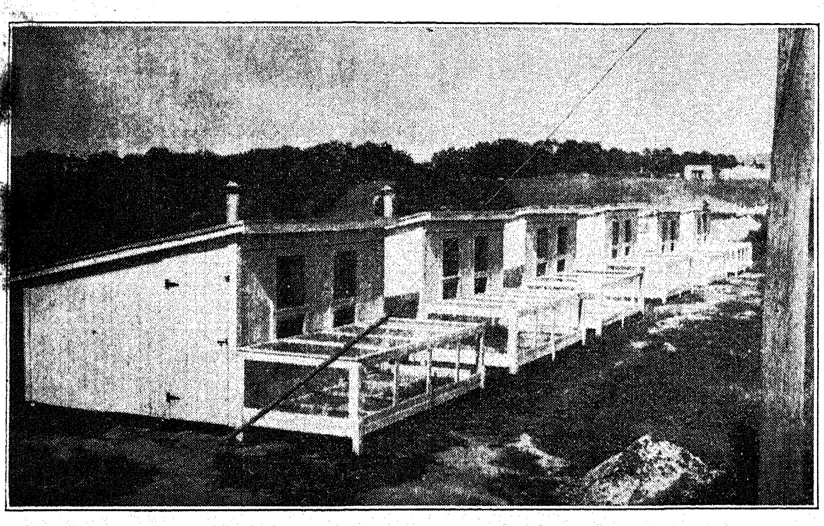
gain by the different groups. The pullets fed the first ration started laying 10 to 12 days later than those fed the complete ration, but they laid about as many eggs during the laying year.

Sometimes the raising of pullets on a moderately restricted amount of feed is advocated. However, this delays the beginning of laying, and it does not seem to make any appreciable saving in the total amount of feed consumed up to the beginning of egg production.[25]

hens, to avoid the spread of disease and parasites.

The greatest danger of feather picking and cannibalism developing comes the first few weeks after the pullets are put in the laying house. Common causes are overcrowding or an inadequate ration.

The cockerels to be retained for breeding are usually selected at the broiler stage. They should be chosen on the basis of vigor, rapid growth,



BROODER HOUSES WITH SUN PORCHES

Rearing chickens in confinement in this manner is advisable only when fresh, uncontaminated pasture cannot be provided. (From Hurd, New York State College of Agriculture, Cornell University.)

Experiments show that when pullets have unlimited range on excellent pasture, such as Ladino clover or Ladino and grass, they may make satisfactory growth and develop properly when fed only grain with mineral supplements after they are 7 to 10 weeks of age.[26] Sometimes, however, pullets thus fed will not grow so rapidly or start laying so soon.

The pullets should be moved to the laying house 1 to 3 weeks before they are ready to lay. They should always be handled carefully, so that they do not become frightened. If possible, the pullets should be housed separately from

early feathering, moderate comb development, and good pigmentation of shanks. It is desirable to retain three times as many cockerels as will be needed for breeding, so that later they can be thoroughly culled. The cockerels should have a separate range, and should be fed about the same as the pullets.

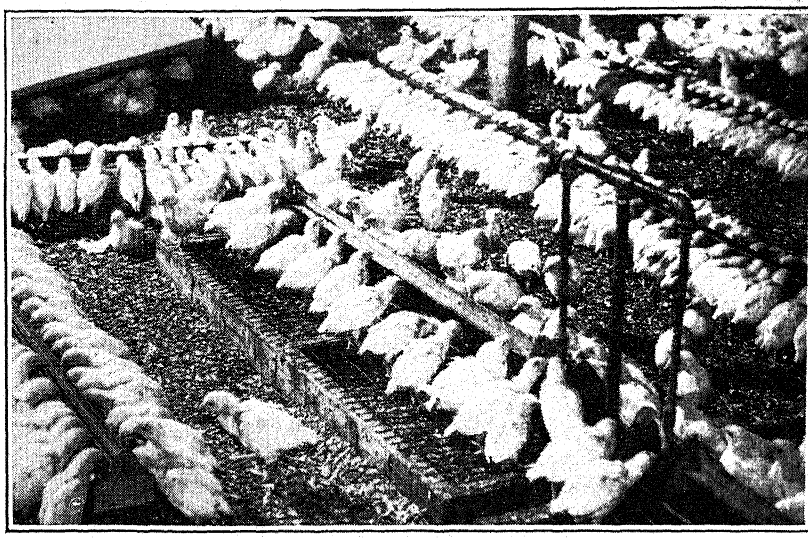
In the case of breeds which have large combs, many poultrymen dub the combs and wattles of cockerels that are to be retained for breeding. This means that most of the comb and wattles are cut off, in order to avoid injury later from freezing or fighting. Males which have been dubbed are usually in better

condition at the beginning of the breeding season and are more fertile than undubbed males. The dubbing is generally done when the cockerels are 8 to 12 weeks old.

1582. Production of broilers.—The production of broilers has become a very important year-around industry in some areas of the United States. In 1954 about 800,000,000 chicks were used for broiler production in only the 14 chief broiler-producing areas of our country.[27]

In addition to the specialized broiler plants, on egg-producing poultry farms the surplus cockerels are generally marketed as broilers.

For specialized broiler production, cross-bred chicks of the heavy breeds are generally used, because of their more rapid growth. A popular cross is produced by mating White Plymouth Rock males to Cornish or other females. Sometimes chicks of the heavy breeds are used instead of cross-breds.



ARRANGEMENT FOR WATERING BROILERS IN LARGE PLANT

In large-scale broiler production, feeding and watering facilities are provided to save as much labor as possible.

The term "broiler" is now commonly used for chickens of either sex which are finished for marketing when 8.5 to 12 weeks old and weighing 3 to 4 lbs. alive. Sometimes the heavier broilers are called "fryers."

Broiler production is chiefly a highly specialized, large-scale enterprise. Such producers have plants in which 10,000 to 20,000 or more broilers are raised at a time, and 4 or even more batches are produced a year. To provide a steady supply of finished broilers throughout the year, chicks are started nearly every week in the important producing areas.

1583. Feeding broilers.—For efficiency in broiler production, it is essential that a ration be used which fully meets all the nutritive requirements for very rapid growth. On such a ration not only is less feed required per pound of gain, but also rapid growth produces tender meat.

The nutritive requirements for chicks and growing chickens have been discussed in detail in the preceding chapter. Further information on the special nutrient needs of chicks and methods of feeding has been given earlier in this chapter. (**1579–1580**)

Essentials in rations for economi-

cal broiler production are: (1) High-energy rations, which are necessary for a maximum rate of growth and for efficiency of gains; (2) protein of excellent quality, which furnishes plentiful amounts of the essential amino acids; (3) a proper supply of minerals; (4) ample amounts of the various needed vitamins, including vitamin B_{12} and also the unidentified vitamins or factors; (5) an effective antibiotic feed supplement. All these requirements for rapid and efficient growth have been fully discussed previously.

The remarkable increase in efficiency of broiler production made possible by the recent discoveries in poultry nutrition has been pointed out in the previous chapter. (1495) Only a few years ago more than 4 lbs. of feed were required on good rations per pound of broiler marketed. Now broilers have been produced on modern, complete rations with only 2.2 lbs. of feed per pound of gain.

All-mash rations are generally used for broilers, and this method of feeding is usually continued until the broilers are marketed. When the chicks are about 6 weeks old, cracked grain is sometimes fed in hoppers, in addition to the mash. This method produces good results when a mash is used that contains about 20 per cent or more protein.[28]

Broilers with yellow color in the skin and shanks are preferred on the market. Therefore, a sufficient amount of feeds that produce yellow color in body tissues should be included in the ration, such as yellow corn, corn gluten meal, and alfalfa meal or alfalfa leaf meal. (1518)

1584. Fattening or finishing chickens.—When the surplus cockerels are marketed as broilers, they can be sold direct from the range if they are in good flesh, or they may be put in pens or crates and fed a special fattening ration for 10 to 14 days or longer. Such a ration is fed when fattening caponettes, or hormonized broilers. (1540) Also, fattening rations are used for the production of capons, and hens and roosters are often fattened thus before they are marketed, in order to improve the quality of the carcasses.

In such fattening the mash may be mixed to a batter with skimmilk, buttermilk, or water, so the birds will eat more feed than if fed a dry mash. The birds are started on the fattening ration carefully, and then after 2 to 4 days they are given twice a day or oftener as much of the batter as they will clean up. Supplying water or milk to drink is unnecessary, except in hot weather, because of the large amount of liquid in the batter.

The ration need not be so nutritionally complete during this brief fattening period as in the growth period. It generally consists mostly of finely-ground grains. Fat is sometimes added to the mash in order to increase the productive energy, and thus hasten the fattening. (1506) No fish oil or fish meal should be included in a fattening ration, to avoid danger of tainting the meat. It is not necessary to supply grit or oyster shell during the fattening period.

1585. Growth of chickens and feed required.—The publication on "*Nutrient requirements for poultry*" by the special committee of the National Research Council, to which references have been made previously, gives the estimates on the next page of the ages at which chickens should reach certain live weights.[29] Also, the approximate amounts of feed are stated, which are required per bird to reach these live weights.

The table shows that White Leghorn females should reach an average weight of 2.5 lbs. at 14.6 weeks of age, and males at 11.1 weeks. The females of the heavy breeds should reach a weight of 3.0 lbs. at 11.3 weeks, and the males at 10.0 weeks.

Up to a weight of 2.5 lbs., White Leghorn females will eat approximately 10.6 lbs of feed, and males 8.1 lbs. To a weight of 3.0 lbs., females of the heavy breeds will consume about 10.0 lbs. of feed, and males about 8.0 lbs.

III. Turkeys

1586. Production of turkeys.—The great increase in the production of tur-

keys for meat which has occurred in this country during recent years has been made possible only through the discoveries concerning poultry nutrition and disease prevention. Instead of being only a holiday treat, turkey meat has now become a staple and economical food.

It will be noted in Chapter XII that according to recent estimates by Jennings of the United States Department of Agriculture, turkeys rank next to pigs in the efficiency with which they convert their feed into protein and energy in food for humans. (352)

It was formerly considered impossible to raise turkeys successfully unless they had free range. However, when free range was provided, there were often very serious losses from blackhead or other diseases or from infection with internal parasites.

With the development of modern, complete rations for poultry, it was found that thrifty turkeys could be raised entirely in confinement or in semi-confinement. These results have made it possible to raise turkeys commercially on an intensive basis in sections where former attempts at large-scale turkey production often failed.

One method of raising young turkeys is to confine them in the brooder house and an adjoining sun porch floored with wire netting until they are ready for market. The house is cleaned regularly to prevent the spread of disease or parasites. This system is preferred when uncontaminated pasture is not available.

In the semi-confinement system the day-old young turkeys, called poults, are started in a brooder house, with or without an attached sun porch. In order to avoid disease and parasites, they are not permitted to touch the ground until they are old enough to go on fresh, uncontaminated pasture, usually at 8 to 12 weeks of age. This system is commonly preferred when clean pastures are available, and when enough turkeys are grown to warrant the extra work of feeding and caring for them on the pasture.

Age to reach certain live weights, and feed required

Average live weight	Age at which the live weight is reached				Quantity of feed required per bird			
	White Leghorns		Heavy breeds		White Leghorns		Heavy breeds	
	Females	Males	Females	Males	Females	Males	Females	Males

1587. Nutrient requirements of turkeys.—Largely because they grow more rapidly than chickens, poults require a greater percentage of protein in their ration than do chicks.[30] Also, their requirements, per pound of feed, for calcium, phosphorus, vitamin A, vitamin D, and riboflavin are higher than those of chicks.

The nutrient requirements of turkeys, as stated in the revised 1954 report of the special committee of the National Research Council, are shown in the following table. It should be noted that these revised standards are estimates of the minimum requirements, and they do not include any margins of safety, such as there are generally in other feeding standards for cattle, sheep, horses, and swine.

In making up practical rations, the

amounts of nutrients provided should be sufficiently greater than these minimum requirements to cover variations in the composition of feeds and differences in the requirements of individual birds. (1498)

On comparing the requirements stated in this table with the requirements of chickens which are given in the preceding chapter, it will be noted that the requirements of poults for protein, vitamin A, vitamin D, riboflavin, calcium, and phosphorus are decidedly higher than those of chicks. (1498) Breeding turkeys require about the same proportion of protein as do breeding hens, but hen turkeys need more vitamin A and vitamin D.

Nutrient requirements of turkeys [1]

	Starting poults 0–8 weeks	Growing turkeys 8–16 weeks	Breeding turkeys
Total protein, per cent [2]	28	20	15
Vitamins			
Vitamin A activity (U.S.P. Units.) [3]	2400	2400	2400
Vitamin D (International Chick Units)	400	400	400
Riboflavin, mg.	1.7	?	1.5
Pantothenic acid, mg.	5.0	?	?
Choline, mg.	750	?	?
Folacin, mg.	0.4	?	?
Minerals			
Calcium, per cent	2.0	2.0	2.25 [4]
Phosphorus, per cent [5]	1.0	1.0	0.75
Manganese, mg.	25	?	15
Salt, per cent [6]	0.5	0.5	0.5

1 These figures are estimates of requirements and include no margins of safety.
2 The protein content of rations for growing turkeys from 16 weeks to market weight may be reduced to 16 per cent.
3 May be vitamin A or carotene.
4 This amount of calcium need not be incorporated in the mixed feed, inasmuch as calcium supplements fed free choice are considered as part of the ration.
5 At least 0.50 per cent of the total feed of starting poults should be inorganic phosphorus. All of the phosphorus of non-plant feed ingredients is considered to be inorganic. Approximately 30 per cent of the phosphorus of plant products is non-phytin phosphorus and may be considered as part of the inorganic phosphorus required. Presumably a portion of the requirement of growing and breeding turkeys must also be furnished in inorganic form.
6 This figure represents salt or sodium chloride added as such or in marine or fermentation products of high sodium chloride content.

Experiments have shown that the vitamin D in cod-liver oil or sardine oil has a lower relative efficiency for turkeys than it does for chickens, in comparison with the efficiency of vitamin D in the form of activated animal sterol. (202)

1588. Protein; amino acids.—The previous table shows that poults require 28 per cent of protein in the ration up to 8 weeks of age, and 20 per cent from 8 to 16 weeks of age. The recommended level of protein in rations for poults is therefore considerably higher than for chicks. (1498) Breeding turkeys need only 15 per cent of protein in the ration, which is the same percentage required by hens.

The special committee of the National Research Council states the requirements of certain of the essential amino acids in a 28-per cent-protein starting ration for poults to be as follows: Arginine, 1.6 per cent; glycine, 1.0 per cent; isoleucine, 0.84 per cent; lysine, 1.5 per cent; methionine, 0.87 per cent, or else methionine, 0.52 per cent, plus cystine, 0.35 per cent; and tryptophan, 0.26 per cent.[29]

The manner in which an amino acid deficiency can be corrected in a practical poultry ration has been discussed in the preceding chapter. (1503)

In recent experiments with poults fed a corn-soybean oil meal type starting ration, satisfactory growth was secured with only 20 per cent protein, when pure methionine and lysine, two of the

essential amino acids, were added.[31] This indicates that the need for the high level of 28 per cent protein in the usual practical rations is to supply sufficient of these amino acids. Synthetic methionine is now available commercially at a price that makes its use practicable in correcting a methionine deficiency in poultry rations. However, the cost of synthetic lysine is yet much too high to make its use practicable.

The results of the experiments in which methionine has been added to practical rations for poults have been similar to the trials with chicks or broilers.[32] (**1504**) In the majority of the tests the feed efficiency has been improved slightly, and in some the rate of gain has been increased a little.

It has been found that a deficiency of lysine in the ration causes a bleaching of the feathers of Bronze poults, resulting in some white feathers.[33] This can be prevented by including in the ration a sufficient percentage of feeds high in lysine, such as meat scrap, tankage, fish meal, or dried skimmilk.

1589. Fiber; high-energy rations.— Turkey poults can make good growth on rations containing a higher percentage of fiber than is satisfactory for chicks. However, with a high level of fiber considerably more feed is required per pound of gain. High-energy rations are therefore generally more economical, unless a ration lower in productive energy is much cheaper.[34]

In a Pennsylvania trial with turkey pullets a ration supplying 882 Calories of productive energy per pound was compared with rations having lower energy contents.[35] The feed efficiency and the hatchability of the eggs were best on the high-energy ration. However, there was not much difference in the egg production, the fertility of the eggs, or in the maintenance of body weight on the various levels of energy.

A Utah experiment shows that after poults are 8 weeks old, they will make satisfactory growth on a ration containing as much as 35 per cent of good-quality alfalfa meal.[36] The rate of gain to 29 weeks of age was as high as with less alfalfa meal, and only a little more feed was required per pound of gain.

YOUNG TURKEYS ON GOOD RANGE

Note the waterer in the foreground, which is on a platform covered with wire mesh. (From Smith, New York State College of Agriculture, Cornell University.)

1590. Minerals.—The requirements of turkeys for calcium, phosphorus, manganese, and salt are shown in the previous table of "*Nutrient requirements of turkeys.*" (1587) It will be noted that in rations for poults to 8 weeks of age and also for growing turkeys 2.0 per cent of calcium is required. This is double the percentage needed by chickens.

The requirement for phosphorus is also much higher than for chickens, being 1.0 per cent of the ration for young poults and also for growing turkeys.

Turkeys cannot tolerate as high a level of salt as can chickens. For example, in a Texas experiment including 2 per cent of salt in a ration for poults caused heavy mortality.[37] More than the recommended percentage of salt, 0.5 per cent, should not be added to the ration.

1591. Vitamins.—Turkeys require the same vitamins as do chickens, and the detailed discussions in the preceding chapter concerning the various vitamins for chickens apply in the main to turkeys as well. However, as will be noted in the table of nutrient requirements of turkeys, their requirement for the different vitamins is greater than in the case of chickens. (1498, 1587)

For example, poults up to 8 weeks old and also growing turkeys from 8 to 16 weeks of age need 2,400 U.S.P. Units of vitamin A activity per pound of ration. This is twice as much as required by young chickens. The vitamin A requirement of breeding turkeys is also higher than for hens.

The vitamin D requirement of young turkeys is especially high, being 400 International Chick Units of vitamin D per pound of ration, while young chickens need only 90 Units. Breeding turkeys also require 400 Units per pound of ration, which is nearly twice as much as hens need.

A deficiency of vitamin D or lack of calcium or phosphorus causes rickets in growing turkeys, and a deficiency of the vitamin in hen turkeys results in thin-shelled eggs and poor hatchability.

Experiments have shown that the vitamin D in cod-liver oil has a lower relative efficiency for turkeys than it does for chickens, in comparison with the efficiency of vitamin D in the form of activated animal sterol.[38]

Young turkeys need somewhat more riboflavin per pound of ration than do young chickens, as will be noted in the tables of nutrient requirements. Also, the riboflavin requirement of turkey poults seems to be increased when an arsonic supplement is added to the ration.[39]

Sometimes young turkeys are affected seriously by the "enlarged hock disorder" a few weeks before they are ready for market. This condition is different from perosis, or slipped tendon. The trouble seems to be due partly to a deficiency of an unidentified vitamin or factor, as the addition of 5 per cent of brewers' yeast has been effective in preventing it in some experiments.[40] In New York studies the adding of niacin, as well as brewers' dried yeast, was more effective than dried yeast alone.[41] On the other hand, in a Washington trial the addition of niacin to a ration did not prevent enlarged hocks.[42]

1592. Antibiotic feed supplements.—A detailed discussion of antibiotic feed supplements in poultry rations has been given in the preceding chapter. (1533–1535) The results from including an antibiotic supplement in rations for poults and growing turkeys have been similar to those secured with chicks and broilers.[43] An effective antibiotic supplement usually seems to increase the rate of gain of poults even more than that of chicks.

Just as in the experiments with chicks, streptomycin has in most trials with poults been less effective than penicillin, aureomycin, terramycin, or bacitracin. Also, as with chicks, in some trials a combination of antibiotic supplements has not been superior to a single effective antibiotic supplement.

An antibiotic supplement produces the most marked increase in growth of poults up to an age of about 8 weeks. However, the best results are secured when the use of the supplement is continued until the turkeys are marketed, just as in the case of broilers.

In the few experiments in which an

antibiotic supplement has been added to rations for hen turkeys, the results have differed, like the results of the trials with hens.[44] It therefore seems doubtful whether the use of an antibiotic supplement for hen turkeys will usually be economical.

Most of the antibiotic supplements are antibiotic-vitamin B_{12} feed supplements, which supply not only an antibiotic or antibiotics, but also vitamin B_{12}. The effect of such a supplement obviously may be due to the vitamin as well as to the antibiotic.

1593. Arsonic supplements.—The use of arsonic supplements in rations for poultry has been discussed in the preceding chapter and also in Chapter XXIII. (**1536, 967**) Very few experiments have thus far been reported in which these supplements have been tested in rations for poults.[45]

In these trials certain arsonic supplements, but not others, have tended to increase the feed efficiency slightly and also in some cases to improve the gains a little.

1594. Hormones.—The effects of certain synthetic sex hormones on poultry have been discussed in the preceding chapter. (**1540**) It is there shown that implanting a pellet or paste of diethylstilbestrol (commonly called "stilbestrol") under the skin of the head or upper neck a few weeks before slaughter usually improves the market finish of cockerels and increases the fatness and tenderness of the meat. Sometimes this treatment is combined with the addition of thiouracil to the ration during the finishing period.

Similar results have been secured in a few trials with young turkeys or with hen turkeys which are marketed at the end of the laying season.[46]

1595. Essentials in turkey production.[47]—For success in turkey production, it is even more necessary than with chickens that great care be taken to provide certain essentials.

Because the requirements of poults for protein, minerals, and vitamins are considerably greater than are those of chicks, the ration must fully meet these needs.

Strict sanitation is essential, or there may be very serious losses from disease. All equipment, including waterers and feeders, should be cleaned and disinfected regularly. This applies also to the incubator and to the brooder houses, before each use.

Feeders and waterers should be placed on screen or slat platforms, to prevent contamination from feces. On the range, feeders and waterers should be moved frequently. The poults should be fenced away from the droppings der the roosts.

Turkeys should be kept enti separate from all chickens. Any de birds should be burned, or else buri in fields that will not be used for tu for 2 years. Screen-floored sunpo attached to the brooder houses aid preventing infection from feces during the first few weeks.

For turkeys, only clean range should be used which has had no poultry on it for 2 years. The range should be well drained and have no stagnant water. Shade should be provided to prevent heat prostration. If possible, birds on range should be rotated to fresh areas during the season.

1596. Feeding growing turkeys.—Turkey poults may be fed the same sort of rations as chicks, except that the proportions of protein, mineral, and vitamin supplements should be larger, as shown previously. Generally, poults are fed a dry turkey-starter mash alone for the first few weeks. Chick-size grain may be supplied in addition, after the birds are 2 weeks old, and whole grain when they are about a month older.

The mash, or the ingredients, except oats, should not be ground very fine, and the mash should not be sticky when moistened. Otherwise, it may stick to the beaks of the poults.

During the first few weeks, oats should be included in the starter mash only if they are very finely ground, or pulverized. In Ohio and Texas experiments mashes with 10 to 20 per cent

of coarsely ground oats caused digestive disturbances and heavy mortality.[48]

After the poults are 8 weeks of age, the turkey-starter mash is usually replaced by a growing mash, which is lower in protein. A mixture of whole grain is commonly fed in addition, but sometimes 2 or more kinds of whole grain are fed instead. Many turkey producers feed pellets in addition to mash, or in place of it.

Grit is fed to poults once or twice a week, or else supplied in separate hoppers. Unless the mash contains ample calcium, oyster shell or limestone grit should be furnished. Plenty of water should always be accessible.

When turkeys are reared in confinement, it reduces the cost and improves their growth if they are fed fresh green feed daily. It is estimated that excellent pasture, such as has been previously recommended, may save 10 to 20 per cent of the concentrates required when turkeys are reared in confinement.[49] (1547)

If turkeys have been raised on a good ration, they need little or no special fattening during the last few weeks before they are marketed. Because of the danger of producing a fishy flavor in the flesh, turkeys should not be fed either fish meal or cod-liver oil or other fish oil, for at least 4, and preferably 8 weeks, before they are marketed.

Instead of marketing turkeys as roasters, at the usual age of about 28 weeks, a few producers market turkey broilers or fryers at the early age of 14 to 16 weeks.

1597. Feeding breeding turkeys.—Breeding turkeys may be fed much the same as hens, except that their rations should have somewhat more vitamin A, vitamin D, and phosphorus. They should not be given so much feed that they become too fat, or they may not lay well in the spring.

About a month before egg production is desired, electric lighting is used, to provide 12 to 14 hours daylight. At this time, the birds are changed from the growing mash to a breeder mash.

The birds should consume about equal weights of mash and grain. If they tend to eat too much grain, the grain hoppers can be kept open only part of each day.

IV. Ducks; Geese

1598. Ducks.—When ducks are raised for the production of meat, the ducklings are generally marketed at 10 to 12 weeks of age, weighing 5 to 6 lbs. A sandy soil is best for duck farms, and the ducks should have access to a body of water, if possible. A somewhat isolated location is desirable, as large flocks of ducks are noisy, and the pens may have an unpleasant smell in summer.

1599. Feeding breeding ducks.—The older method of feeding breeding ducks was to feed a wet mash in the morning and in the afternoon, and also to feed a mixture of grains in addition. This method has been largely replaced by the labor-saving method of feeding dry pellets in hoppers, with grain fed in hoppers in addition.

The feed hoppers are kept open not more than an hour in the morning and 2 hours in late afternoon. About 90 lbs. of pellets are fed to each 10 lbs. of grain during the laying season, and 50 lbs. of pellets to each 20 lbs. of grain during the rest of the year.

A popular mash for the mash-feeding method has the following ingredients per ton of feed:[50] 425 lbs. ground yellow corn, 300 lbs. wheat bran, 200 lbs. wheat standard middlings, 300 lbs. wheat red dog, 200 lbs. low-fiber ground oats, 150 lbs. soybean oil meal, 75 lbs. meat scrap, 120 lbs. alfalfa meal, 150 lbs. dried skimmilk, 70 lbs. pulverized limestone, and 10 lbs. salt. The mash should have about 18 per cent total protein and should contain 650 A.O.A.C. chick units of vitamin D per pound. If green feed is available, the alfalfa meal may be omitted.

The ducks should eat about twice as great a weight of mash as of grain. They should be provided with oyster shell or high-grade limestone grit, and also with granite grit and screened gravel. Good pasture is very desirable

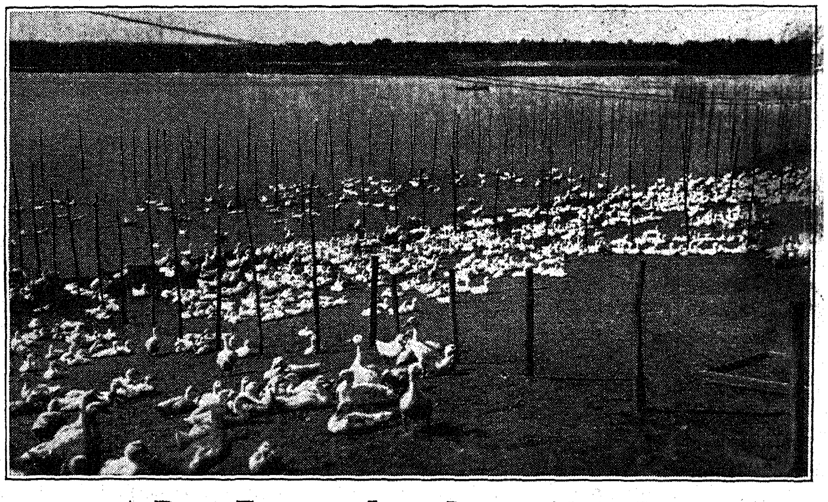
for raising breeding ducks, if it can be provided.

1600. Feeding ducklings.—As in the case of breeding ducks, the feeding of dry pellets in hoppers has largely replaced the feeding of wet mash on commercial duck farms.

Much less information is available concerning definite nutrient requirements of ducks than for chickens, or even turkeys. The special committee of the National Research Council gives the following estimates of certain nutrient requirements in rations for ducklings, per pound of feed: Total protein, 17 per cent; vitamin D, 100 International Chick Units; riboflavin, 1.8 milligrams; pantothenic acid, 5.0 milligrams; niacin, 25.0 milligrams; and pyridoxine, 7.2 milligrams.[29]

A bowed-leg disorder in ducklings raised on wire mesh floors has been found in New York studies to be due apparently to a niacin deficiency.[51] This was prevented by adding 10 milligrams of synthetic niacin per pound of ration, or else 5.0 to 7.5 per cent of brewers' dried yeast, which is rich in niacin. Because of these results, the amount of niacin previously stated for ducklings is twice as high as for chicks.

In the pellet-feeding method, the ducklings have access at all times to dry pellets, fed in hoppers, and to water. No grain is fed separately. At first "starting pellets" are fed, and when the ducklings are 2 weeks old, "duck grower" pellets are used. For the final 2 weeks of fattening, these are replaced by fattening pellets.



A Duck Farm on Long Island, New York

Many large-scale duck farms are located on Long Island, where the conditions are very favorable for duck production. (From Hurd, New York State College of Agriculture, Cornell University, New York.)

In the older method the ducklings are raised on a wet mash which is fed 4 or 5 times a day during the first week and then 3 or 4 times daily. Any feed left should be removed after each feeding. No grain is fed, but chopped fresh green feed or cooked vegetables are sometimes supplied.

A suitable mash for the first 6 weeks contains the following ingredients per ton:[50] 690 lbs. ground yellow corn, 300 lbs. wheat bran, 200 lbs. wheat standard middlings, 300 lbs. wheat red dog, 150 lbs. soybean oil meal, 100 lbs. meat scrap, 120 lbs. alfalfa meal, 100 lbs. dried skimmilk, 30 lbs. pulverized limestone, and 10 lbs. salt. After the ducklings are 6 weeks old, the amount of meat

scrap may be reduced to 75 lbs., the alfalfa meal to 100 lbs., and the dried skimmilk to 50 lbs., while the ground corn is increased to 785 lbs.

An antibiotic feed supplement apparently has very much less effect upon ducklings than in the case of poults or chicks.[52]

1601. Geese.—Geese are generally raised where they can have good range or pasture, and where the mature geese pick up most of their living, except during the winter. Geese do not do well in confinement. When pasture is no longer available, the geese should have such roughage as vegetables, alfalfa or other legume hay, silage, or chopped corn stover. Enough grain, such as oats and corn, wheat or barley should be fed to keep the geese in thrifty condition. Before the laying season starts, the amount of grain should be increased and a mash should be fed once a day. A duck or hen mash is satisfactory. Grit and oyster shell should be supplied at least when the geese are laying, and preferably at all times. Water for drinking should always be provided.

The goslings may be fed a chick or duckling mash in wet form, or they can be started on stale bread soaked in milk or water, or on such a mash as 4 parts of ground corn and 1 part of wheat middlings. Plenty of green feed should always be supplied. After 2 to 3 weeks, the goslings will not need any mash if they have plenty of grass or other good pasture.

Differing from the results with ducklings, an antibiotic feed supplement appreciably increases the rate of growth of goslings.[53]

For about 2 or 3 weeks before the young geese are marketed, they may be fattened by confining them in pens and feeding them liberally. A common ration is one feeding a day of a moist mash (such as two-thirds ground corn and one-third wheat middlings), with two feedings a day of a mixture of corn and other grains.

QUESTIONS

1. What grains are used chiefly for feeding poultry in your region? What is the relative feeding value of these grains?
2. About how much feed is needed daily per 100 hens, at 50 per cent egg production; by hens of the light breeds; by hens of the heavy breeds?
3. Describe the mash-and-scratch-grain method of feeding laying hens.
4. What is the advantage and what is the disadvantage of feeding a limited amount of grain in hoppers, instead of in the litter?
5. Discuss the free-choice method of feeding layers.
6. When is the use of wet mash advantageous?
7. Discuss the advantages and disadvantages of all-mash rations for layers.
8. Discuss the use of artificial light for layers.
9. What are the chief items of expense in producing eggs, and what proportions are they of the total gross cost?
10. What are some of the important points to consider in selecting breeding stock?
11. How should rations for breeding hens differ from rations for the production of market eggs?
12. State the important points in saving eggs for hatching.
13. At what time of year should pullets for egg production ordinarily be hatched?
14. Describe the method of hatching eggs with hens.
15. Describe: (a) The artificial brooding of chicks; (b) brooding chicks with hens.
16. Discuss the nutrient requirements of chicks.
17. State the important points in feeding the chicks.
18. Discuss the raising of pullets and cockerels.
19. Describe the usual method used in broiler production.
20. About how much feed is required per pound of live weight in the production of broilers?
21. How do turkeys rank with other livestock in the efficiency of meat production?
22. Compare the nutrient requirements of young turkeys and of chicks.
23. Describe the 2 systems commonly used in raising turkeys.
24. Discuss the requirements of poults for: (a) Protein and amino acids; (b) energy; (c) minerals; (d) vitamins.
25. What results have been secured from adding an antibiotic feed supplement to rations for poults?

26. What use is sometimes made of hormones in producing market turkeys?
27. State some of the essentials for success in turkey production.
28. Discuss the feeding of: (a) Growing turkeys; (b) breeding turkeys.
29. What 2 methods are used in feeding breeding ducks?
30. Describe the methods of feeding ducklings.
31. What important differences are there in the feeding of geese and chickens?

APPENDIX

Table I. Average Composition of American Feeds; Digestible Nutrients; Mineral and Fertilizing Constituents; Digestion Coefficients

New compilation of composition and digestibility of feeds.—In order to present as accurate and complete information as possible concerning the composition of all our important feeds, a new and exhaustive compilation of available data has been made for this volume.

The first compilation of analyses of American feeds made by the author and associates was published in 1915 in the [illegible] edition of *Feeds and Feeding*. This was superseded by a new compilation published in 1936 in the 20th edition of *Feeds and Feeding*. In turn, this was replaced by another new compilation published in 1948 in the 21st edition of the book. The work on this one table has now extended over a period of more than 40 years.

The great mass of data utilized in the preparation of this table is evident from the fact that time equivalent to one person working steadily for more than twelve years has been required in the compilation and averaging of the data.

The author wishes to acknowledge the invaluable help rendered by his wife, Elsie B. Morrison, and by his son, Dr. Spencer H. Morrison, in the compilation of these and other data. His son, Roger B. Morrison, also aided in previous compilations.

Sources of data.—These compilations include analyses published in the bulletins and reports of the State Experiment Stations, the United States Department of Agriculture, the Departments of Agriculture of certain states, and various scientific journals. Data for a few feeds, for which American analyses are not available, have been taken from foreign sources.

Recent analyses of some feeding stuffs show that the composition has changed since the previous compilations were published. In all such cases, the older analyses have been discarded, and the new averages are based on only the recent analyses.

In certain feeds, the change in composition has been due to the general introduction of new varieties. The most striking example of this is dent corn. The present hybrid varieties, which are now generally grown, are decidedly lower in protein than the older open-pollinated varieties. (682)

In the case of certain by-product feeds, the composition has been changed appreciably by modifications in the manufacturing processes. Thus, the fat content of various oil meals produced by the expeller process or by the hydraulic process is lower than some years ago.

Where information is available, separate averages are given for the various grades of a feeding stuff. Thus, separate averages are given for the most important forage crops cut at different stages of maturity; for hay of various qualities; for high-grade and lower-grade concentrates of the same name; etc. In this table the scientific names of the various plants are not stated where they are given in the discussion of the particular feeds in the body of the text.

Cooperation with National Research Council.—The Committee on Feed Composition of the National Research Council, of which the author is a member, undertook some years ago a compilation of the data concerning the composition of American concentrates. These data were secured chiefly from feed manufacturers who cooperated in the undertaking.

In order to present the most comprehensive data possible, unpublished

data which were compiled by the Committee were combined with data compiled by the author and associates. It was planned that the complete combined data would be published by the Committee and also in *Feeds and Feeding*.

Unfortunately, the Committee was unable to finish the compilation and to publish it in complete form. This was because of the sudden death of Mr. Frank E. James, the secretary of the Committee, who had compiled most of the data. Also, funds were insufficient to complete the undertaking, except for the detailed study of the composition of dent corn, which has been mentioned previously. (**682**)

The Committee has recently been able to undertake another compilation of the composition of American feeds, because of funds furnished by the United States Department of Agriculture. The author has again made available to Mr. Donald F. Miller, technical secretary of the Committee, data which has been compiled for this 22nd edition of *Feeds and Feeding*.

A preliminary report on the composition of concentrate by-products has recently been issued by the National Research Council, and other reports are in preparation. The author has used data from the report on concentrate by-product feeds in the compilation of Appendix Tables IV and V.

Dry matter, digestible protein and total digestible nutrients.—The figures for dry matter, digestible protein, and total digestible nutrients are printed in bold-face type and are given first in this table, since these are the figures commonly used in computing balanced rations. Explanations of the methods of computing digestible protein, total digestible nutrients, and nutritive ratios are given in Chapter III. (**63, 65**)

The figures for digestible nutrients have been computed by means of the digestion coefficients obtained in experiments with cattle and sheep. However, these figures may also be used in computing rations for horses and swine and according to the feeding standards given in Appendix Table III. (**62**) Where no digestion coefficients are available for a feed, or such data seem unreliable, the digestion coefficients for a similar feed have been used and that fact is indicated by an asterisk (*).

Digestion coefficients.—Where reliable digestion coefficients are available for a feed, the average digestion coefficients are given on the right-hand page of the table, opposite the average analysis of the feed, which is shown on the left-hand page. These averages are for the experiments conducted with cattle and sheep. Relatively few digestion experiments have been conducted with other livestock.

The author and associates have brought down to date for this volume their compilation of the digestion coefficients secured in experiments conducted in this country. For some feeds [illegible] data on digestibility are lacking, or [illegible] inadequate in amount. In these cases the author has been aided by a comprehensive compilation made by Dr. B. H. Schneider of digestion coefficients secured in experiments not only in this country but also in other countries. This compilation, entitled *Feeds of the World, Their Digestibility and Composition*, was published by West Virginia University in 1947.

For a considerable number of feeds, the digestion coefficients given in *Feeds and Feeding* are taken, with Professor Schneider's permission, from his compilation. Such cases are indicated by a dagger (†) after the "number of trials."

Where Dr. Schneider's data are used in this table, the coefficients obtained in experiments with cattle and with sheep have been combined. These are given separately in Professor Schneider's publication. The coefficients for cattle and sheep have been combined in this table because experiments have shown there is less difference in digestibility of most feeds by cattle and by sheep than there is in digestibility by individual animals of the same species. (**106**)

In the compilation of American digestion coefficients made by the author and associates, some of the older data have been discarded. These experiments

were conducted many years ago, before the discoveries had been made concerning the importance of vitamins and minerals in animal nutrition. Perhaps for this reason, in some cases these old digestion coefficients do not agree with our present knowledge concerning the actual values of certain feeds for livestock.

Mineral and fertilizing constituents.—Detailed information is given in Appendix Table IV concerning the mineral content of the important feeds. For convenience in computing rations, the percentages of calcium and of phosphorus in various feeds are also given in Appendix Table I, so far as data are available.

The average percentages of nitrogen and potassium are also given, so that the fertilizing value or the manurial value of the various feeds can be readily determined. (988)

Variations in composition.—In using this table it must be borne in mind that individual lots of any particular feeding stuff may differ in composition from the average, as has been shown previously. (96–100) In the case of roughages, the variations are apt to be especially large in the content of calcium and of phosphorus. Also, much less information is available concerning the mineral content of various feeds than concerning the amounts of other nutrients they contain. The figures for calcium and phosphorus therefore merely indicate the approximate percentages that are present in the different feeds when produced on soil reasonably well supplied with these minerals.

TABLE I. Average composition and digestible nutrients

Feeding stuff	Total dry matter	Dig. protein	Total dig. nutrients	Nutritive ratio	Average total composition					No. of anal.
					Protein	Fat	Fiber	N-free extract	Mineral matter	
Dry Roughages	Per ct.	Per ct.	Per ct.	1:	Per ct.	Per ct.	Per ct.	Per ct.	Per ct.	
Alfalfa hay, all analyses	90.5	10.9	50.7	3.7	15.3	1.9	28.6	36.7	8.0	1,288
Alfalfa hay, very leafy (less than 25% fiber)	90.5	12.8	52.7	3.1	17.5	2.4	22.7	39.5	8.4	219
Alfalfa hay, leafy (25–28% fiber)	90.5	11.7	51.2	3.4	16.0	2.1	27.2	36.8	8.4	294

Table II. Estimated Net-energy Values and Feed Evaluation Factors

Estimated net-energy values.—For the reasons stated in Chapter III, it is the belief of the author that net-energy values are more accurate than total digestible nutrients for comparing the value of a roughage with that of a concentrate for productive purposes. (77–80) This may also be the case when a high-grade concentrate, containing but little fiber, is to be compared with a concentrate which has appreciably more fiber.

The following table of estimated net-energy values of the most important feeding stuffs has therefore been prepared by the author. These estimates are based upon a study of all the available data that provide information concerning the relative values of these feeds for productive purposes. It should be distinctly understood that many of the values are only approximate and are subject to revision and change, as additional data may become available.

It will be noted that the first two columns of figures give the percentage of dry matter and the percentage of digestible protein in each feed. These values are the same as those given in Appendix Table I, and they are repeated here for ease in computing rations according to the net-energy method, by the use of the net-energy feeding standards presented in Appendix Table III. The figures for digestible protein are the values for *digestible crude protein,* and not *digestible true protein.* (18)

These data indicate the relative net-energy values of the various feeding stuffs when each feed is used in a complete, well-balanced ration, which provides adequate supplies of protein, minerals, and vitamins. If any feed is improperly used or if it forms part of a ration that has nutritive deficiencies, its value may be much less than shown in this table. Also, when a protein-rich feed is fed in great excess of the amount necessary to balance the ration, it may have a considerably lower net-energy value than here estimated.

Attention should be called to the fact that these estimated net-energy values indicate merely the worth of the various feeds as sources of energy, and do not take into consideration the values of the feeds as sources of protein, minerals, and vitamins. Thus, the high-grade protein-rich concentrates have no higher net-energy values than such feeds as corn and wheat, which are relatively low in protein.

It should also be borne in mind that net-energy values do not indicate the relative efficiency of different feeds for maintaining farm animals in cold weather. (75) In comparing the values of feeds for maintenance, the total digestible nutrient values given in Appendix Table I should be used.

These net-energy values are primarily for cattle and sheep, but may also be employed in computing rations for horses and swine, when used with the net-energy recommendations given in the last column of the Morrison feeding standards. (Appendix Table III.)

Net-energy values for dairy cows.—As has been shown in Chapter III, the various feeding stuffs have materially higher net-energy values for milk production than for the fattening of animals. (78) However, the relative net-energy values of most feeds for milk production and for fattening are probably not far different. Where it is believed that the relative net-energy value of a particular feed for dairy cows differs materially from its value for fattening cattle or sheep, the estimated net-energy value of the feed for dairy cows is shown separately.

It seems probable that the relative net-energy value, or productive value, of good-quality hay for dairy cows is somewhat higher in relation to the values of concentrates, than in the case of fattening cattle and sheep. However, there is not sufficient definite information on this question to warrant separate figures for the net-energy value of such hay for dairy cows.

Net-energy values of roughages.—In the case of dry roughages, these values are based upon the results se-

cured when the roughages are fed in mangers or racks so as to prevent undue waste. The estimated value for each roughage takes into consideration the amount of the feed that is usually refused when it is thus fed. For such coarse roughage as dry corn fodder, dry corn stover, sorghum fodder, or sorghum stover, the estimates are for roughage that has been chopped or shredded to reduce the wastage. Likewise, the values for the various grains are based upon the grain being ground or crushed when such preparation is necessary to prevent poor utilization.

Estimating net-energy values.—It has been shown previously that the net-energy values have been actually determined for only a very few feeds by investigations with a respiration apparatus or a respiration calorimeter. Also, probably because of the complex nature of such investigations, there have been rather wide differences in the net-energy values thus directly determined for these few feeds. In arriving at the net-energy values given in this table, it has therefore been necessary to utilize all possible data bearing on the values of the various feeds for productive purposes.

Where the relative values of different feeds have been definitely determined by means of a sufficient number of suitable feeding experiments, the net-energy values have been based primarily on these experiments. For other feeds the values have been computed from the content of total digestible nutrients given in Appendix Table I, by the use of factors based on the chemical composition of the particular feeding stuff and on all available information concerning its feeding value.

In making these estimates careful consideration has been given to the net-energy values, or production values, computed by Fraps. (**86**) Due attention has also been given to the estimates made many years ago by Kellner and Armsby and to the Scandinavian feed-unit values. (**82–84**)

Feed evaluation constants.—In order to select economical rations for livestock, it is necessary to determine which of the available feeds that are otherwise satisfactory provide nutrients at least expense. It has been emphasized previously that the best guides to the relative values of various feeds for any class of stock are furnished by the results of actual feeding experiments with that particular class of stock. (**58–59**) Extensive summaries of such experiments are therefore presented in Part II of this volume, which show the results that have been secured with most of the important feeding stuffs when fed to the various classes of stock.

The relative values of the same two feeds for various classes of farm animals may differ to a considerable extent. Before deciding upon the feeds to use in a ration for any kind of stock, one should therefore find what definite information is given in Part II concerning the values of the different available feeds for the particular kind of livestock.

The relative values of many feeds have not yet been determined accurately for the various classes of stock. In deciding which of such feeds are most economical, one must base his judgment on the amounts of digestible nutrients they furnish and on the general information that is available concerning the usefulness of the respective feeds for the particular class of stock.

When protein-rich feeds are more expensive than feeds low in protein, a method of comparison should be used that considers both the amount of digestible protein in a feed and also the amount of total digestible nutrients or net energy it supplies. The Petersen method of valuing feeds, which has been explained in Chapter XII, is a convenient method of making such comparisons. (**336**) The fourth and fifth columns of figures in the following table therefore give the constants, or factors, for evaluating the most important feeds by this method.

These constants have been computed with dent corn of Federal Grade No. 2 and solvent-process soybean oil meal as the base or standard feeds. It is the belief of the author that net-energy values provide a more accurate basis

for feed evaluation than do total digestible nutrients. These constants have therefore been computed from the average percentages of digestible protein and the estimated net-energy values which are given in the second and third columns of this same table.

The method of using these constants in comparing the economy of various feeds has been explained in Chapter XII. (338–342)

Using feed evaluation constants.—To illustrate the use of the feed evaluation constants further, let us assume that ground dent corn (Grade No. 2) is worth $58.00 per ton and that solvent-process soybean oil meal costs $75.00 per ton. We wish to find the approximate value of brewers' dried grains for dairy cows in comparison with these base feeds, considering its content both of digestible protein and of net energy.

First, multiply $58.00, the price of ground corn per ton, by 0.374, the figure given for brewers' dried grains for *dairy cows* in the fourth column of figures in the table, entitled "Constant for corn." This gives us $21.69. We next multiply $75.00, the price of soybean oil meal per ton, by 0.464, the "Constant for soybean oil meal." This gives us $34.80. We then add these amounts together, and have $56.49 as the approximate value per ton of brewers' dried grains for dairy cows, in comparison with corn and soybean oil meal at the prices assumed.

When there is a minus sign before either the "Constant for corn" or the "Constant for soybean oil meal" the product is to be subtracted, instead of being added. For example, in the case of fish meal, all analyses, the "Constant for corn" is—0.457 and the "Constant for soybean oil meal" is 1.349. Multiplying $58.00, the price of corn per ton, by the constant—0.457, we have as the result—$26.51. Multiplying $75.00, the price of soybean oil meal per ton, by 1.349, gives us $101.18. Subtracting $26.51 from $101.18, we have $74.67 as the approximate value per ton of fish meal.

Net-energy factors in last column.—When protein-rich feeds cost no more than protein-poor feeds, the factors given in the last column of figures should be used for determining the relative values of feeds, instead of the constants in the fourth and fifth columns. These factors show the relative amount of net energy furnished by each feed, in comparison with dent corn of Federal Grade No. 2 taken as 100 per cent.

To illustrate the manner of using these "Net-energy factors" for valuing feeds, let us find the value as a source of net energy for fattening cattle of kafir grain, in comparison with dent corn of Federal Grade No. 2 at $58.00 per ton.

The net-energy factor for kafir in the last column of the table is 97.1 per cent, which means that kafir supplies approximately 97.1 per cent as much net energy as does No. 2 dent corn. Taking 97.1 per cent of $58.00, we find that the value of kafir as a source of net energy is about $56.32, in comparison with No. 2 corn at $58.00 per ton.

TABLE II. Estimated net-energy values and feed evaluation factors

	Dry matter	Digestible protein	Est. net energy per 100 lbs.	Feed evaluation factors: Constant for corn	Constant for soybean oil meal	Net energy factor
Dry Roughages	Per ct.	Per ct.	Therms			Per ct.
Alfalfa hay, all analyses	90.5	10.9	40.6	0.296	0.212	50.7
Alfalfa hay, very leafy (less than 25% fiber)	90.5	12.8	43.5	0.286	0.259	54.3

TABLE III. MORRISON FEEDING STANDARDS FOR FARM ANIMALS

The author first presented in 1915 a set of feeding standards for the various classes of livestock. These standards were revised in 1922 and in 1936. In 1948 the standards were again revised, and calcium, phosphorus, and carotene allowances were added to the recommendations. Certain changes have again been made in the standards presented in this edition of *Feeds and Feeding*, on the basis of recent data concerning the nutrient requirements of certain classes of livestock.

These standards have been prepared by the author to serve as guides in the computation of balanced rations for the practical feeding of the various classes of livestock. It should be distinctly understood that they are not statements of the theoretical minimum nutrient requirements of animals under the most optimum conditions.

It has been emphasized in the various chapters of this volume that feeding stuffs of the same name may differ appreciably from the average composition. Individual animals of the same kind also differ to some extent in ability to digest and utilize feed. To serve as safe guides in stock feeding, the recommendations made in feeding standards should therefore not be statements of the theoretical nutrient requirements, but should provide a margin of safety to cover such differences.

It is believed that the recommendations in the Morrison standards provide reasonable margins of safety.

It should be pointed out that in certain tables of nutrient requirements of livestock, the amounts of nutrients stated are the estimated minimum requirements. In using such tables in making up practical rations, these minimum amounts must be materially increased to provide margins of safety. (1498)

Minimum and more liberal recommendations.—It will be noted that both minimum and more liberal recommendations are given for dry matter, digestible protein, and total digestible nutrients (or net energy). When protein-rich feeds are not unduly expensive in comparison with feeds low in protein, it is wise to supply enough digestible protein to bring the protein of the rations well up toward the higher figures in the standards. On the other hand, when protein-rich feeds are unusually expensive in comparison with farm grains or other feeds low in protein, it may be more economical to provide only enough digestible protein to meet the lower recommendations. (343)

Unless concentrates are very high in price in comparison with roughages, it is generally advisable to include a sufficient amount of concentrates in rations to provide as much total digestible nutrients (or net energy) as recommended in the higher figures of the standards. On the other hand, when grain and other concentrates are unusually high in price in comparison with roughage, it may be most economical to supply no more total digestible nutrients (or net energy) than is recommended in the lower figures. (344)

In general, when as much total digestible nutrients are furnished as recommended in the higher figures, there should be sufficient protein in the ration to approach the higher figures for digestible protein given in the standards.

As the information concerning the requirements of farm animals for calcium, phosphorus, and carotene is still very limited, no range is given in the allowances of these nutrients. The allowances stated show merely the approximate requirements for each class of livestock.

Net-energy recommendations.—For the convenience of those desiring to compute rations according to the net-energy method, the last column of figures in the standards shows the amounts of net energy, expressed in therms, which are advised for various classes of stock. In computing rations by the net-energy method, the net-energy values of feeding stuffs given in Appendix Table II should be used, instead of the total digestible nutrient values given in Appendix Table I.

For the reason stated in Chapter III,

total digestible nutrient values, instead of net-energy values, should always be used in computing maintenance rations for wintering farm animals in sections where the climate is cold. (75) For this reason the net-energy recommendations for wintering various classes of stock are given in parentheses.

Computing economical balanced rations.—Before attempting to work out economical balanced rations for any class of stock, it is important to study carefully the explanations and general hints given in Chapters XI and XII. It is impossible to compute satisfactory balanced rations if reliance is placed only on the mathematical recommendations of any feeding standard. It is emphasized in these chapters that other factors are just as important in determining the efficiency of a ration as are the amounts of digestible protein and of total digestible nutrients (or net energy). Attention must also be given to the general suitability of the feeds to the particular class of stock, to the content of minerals and vitamins in the ration, and in the case of swine and poultry to the quality of protein.

The special rules and hints on feeding the particular class of stock, which are given in the respective chapters of Part III, should be carefully consulted before proceeding to work out a balanced ration. For convenience the following references to important articles discussing balanced rations for the various farm animals are here given:

- Dairy cows, **1008–1048, 1069–1080**
- Dairy calves, **1110–1122**
- Dairy heifers, **1145–1150**
- Beef breeding cows, **1159–1160, 1210–1215**
- Growing beef cattle, **1159–1177, 1219–1223**
- Fattening cattle, **1159–1187, 1226–1237, 1252**
- Breeding ewes, **1264–1266, 1268, 1274–1281, 1304–1308, 1312**
- Fattening lambs, **1264–1265, 1267–1285, 1331–1336**
- Work horses and mules, **1345–1352, 1359–1364**
- Brood mares, **1365**
- Growing colts, **1371–1373**
- Brood sows, **1381–1390, 1397–1417, 1455–1466, 1478–1480**
- Growing and fattening pigs, **1381–1425, 1449–1453, 1481–1487**

Guides to proportions and amounts of concentrates and roughages.—In computing rations one should have in mind the approximate amounts of roughages and of concentrates required by the various classes of animals. It has been shown in the experiments summarized in Part III that for dairy cows and for fattening cattle or lambs the proportion of concentrates to roughages that will be most profitable depends chiefly on two factors. The first is the relative cost of concentrates and roughages, and the second is the quality of the roughage which is available.

In general, the following will indicate the approximate amounts of concentrates and roughages required by the various classes of livestock. Additional suggestions are given in the Example Rations in Appendix Table VII.

Dairy cows in milk will eat about 2 lbs. of good-quality dry roughage daily per 100 lbs. live weight. Silage may be substituted for dry roughage at the rate of 3 lbs. of silage for 1 lb. of dry roughage. A common rule is to feed 1 lb. of hay and 3 lbs. of silage daily per 100 lbs. live weight. Sufficient concentrates should be fed in addition to bring the nutrients up to the standard. (See the *"Grain feeding table for cows not on pasture,"* Appendix Table VIIIa.)

If the roughage is of especially good quality, dairy cows will eat as much as 2.5 lbs. of hay equivalent daily per 100 lbs. live weight, and they then need correspondingly less concentrates. On the other hand, if the roughage is of poor quality, they may eat no more than 1.5 lbs. of hay equivalent daily per 100 lbs. live weight. Their concentrate allowance must then be increased over the amount needed with good roughage.

The amounts of concentrates required daily by cows producing different amounts of milk of the various fat percentages are shown in the grain feeding tables given in Appendix Table VIII.

Dairy calves need a liberal amount of concentrates in addition to plenty of well-cured hay, until they are at least 6 months of age.

Dairy heifers from 6 months to a year of age should be fed 2 to 3 lbs. of concentrates per head daily in addition to an abundance of good roughage. If the roughage is of only fair quality, 4 to 5 lbs. of concentrates per head daily may be needed to produce normal growth. Heifers over a year of age can be wintered, up to 3 or 4 months before calving, on good roughage alone. With roughage which is only fair in quality, 2 to 4 lbs. of concentrates should be fed per head daily in addition.

Beef breeding cows may be wintered satisfactorily on roughage of reasonably good quality, without any concentrates. If the roughage is low in protein, 1 lb. per head daily of protein supplement should be fed, and with poor roughage a small amount of grain may be needed in addition.

Beef calves and yearlings will make fair gains when wintered on roughage alone, if it is of good quality. If the cattle are to be fattened early the next summer, it is usually best to feed in addition a sufficient amount of grain or other concentrates during winter to keep them improving in condition, or degree of fatness. A small amount of protein supplement should be fed when needed to balance the ration.

Fattening cattle should receive 2.1 lbs. or more of concentrates and dry roughage (or equivalent in silage) daily per 100 lbs. live weight, the allowance of concentrates ranging from less than 1 lb. to 1.7 lbs. or more daily per 100 lbs. live weight, depending on the rate of gain desired and the character of the roughage.

Breeding ewes may be wintered satisfactorily on good roughage alone up to 4 to 6 weeks before lambing, if they are in good condition in the fall. During the 4 to 6 weeks before lambing, 0.5 to 0.75 lb. of a suitable concentrate mixture should be fed per head daily. Ewes, not on pasture, that are nursing lambs need 1.0 lb. or more per head daily of concentrates in addition to good roughage.

Fattening lambs averaging 70 to 75 lbs. in weight will consume about 1.4 lbs. per head daily of hay or other dry roughage, when fed all the grain they will eat. They will eat 2.3 lbs. or more of hay per head daily when the grain allowance is restricted. The amounts of feed eaten by smaller or larger lambs will be roughly proportional to their live weights.

Work horses and mules should be fed approximately the following amounts daily of concentrates (including grain and other concentrates) and of hay, per 100 lbs. live weight:

At hard work, 1.00 to 1.40 lbs. of concentrates and about 1.00 lb. of hay.

At medium work, 0.75 to 1.00 lb. of concentrates and about 1.00 to 1.25 lbs. of hay.

At light work, 0.40 to 0.75 lb. of concentrates and 1.25 to 1.50 lbs. of hay.

Idle, chiefly or entirely on roughage, unless it is of poor quality, when some grain must be used.

Swine can make but very limited use of dry roughage, except in the case of brood sows not nursing litters. However, it is very important under most conditions that swine not on pasture be supplied with well-cured legume hay as insurance against any lack of vitamins. The proportion of legume hay that should be included in rations for growing and fattening pigs not on pasture will range from 5 per cent to 10 or 15 per cent, depending on the need of vitamin supplements in the ration. **(1417)** Dry-lot rations for pregnant sows should have at least 10 to 15 per cent of legume hay.

Poultry.—Good-quality alfalfa meal or alfalfa leaf meal, or that from other legumes, is commonly included in poultry rations to supply carotene and to aid in furnishing other vitamins. Otherwise, dry roughage is not generally used in poultry rations.

Sources of recommendations in the standards.—These standards are based

chiefly upon extensive studies, made by and under the supervision of the author, of the results of feeding experiments and other investigations that supply information concerning the nutrient requirements of the various classes of stock. Information is given in the respective chapters of Part III concerning the basis for the recommendations made in the standards for the various classes of stock.

The reports on *"Recommended Nutrient Allowances for Domestic Animals,"* made by special committees of the National Research Council, have been carefully considered in the revision of the standards. Generally, the recommendations for calcium, phosphorus, and carotene are the allowances advised by these committees.

Standards for dairy cows.—The amounts of nutrients required for a cow producing a given amount of milk which contains a certain percentage of fat are found as follows: Add together the maintenance requirements for a cow of the particular live weight (shown in Division **1A** of the standards), and the requirements for producing the given amount of milk (computed from Division **1B**).

For cows during the last 2 to 3 months of pregnancy, the additional allowances stated under Division **1C** should be added to the allowances for maintenance and the allowances for any milk produced.

To illustrate the method of using the recommendations under Division **1A** and Division **1B** of the standards, let us find the amount of digestible protein advised under usual conditions for a 1,200-lb. cow producing 30 lbs. of 3.5 per cent milk daily. As stated in the column headings, the higher amounts of digestible protein and of total digestible nutrients given in the standards are advised under usual conditions. The lower amounts are the minimums advised when protein-rich feeds are unusually expensive, or, in the case of total digestible nutrients, when concentrates are unusually expensive in comparison with hay or other roughages.

For the maintenance of a cow of this live weight, the standard recommends 0.76 lb. digestible protein. For producing each pound of 3.5 per cent milk, the allowance recommended is 0.046 lb. digestible protein. Therefore 30 times this amount, or 1.38 lbs. digestible protein, will be required for the production of 30 lbs. of milk. Adding together the maintenance requirement (0.76 lb.) and the production requirement (1.38 lbs.), we have a total of 2.14 lbs. digestible protein, which is the amount advised for such a cow under usual conditions.

For a cow during the last 2 or 3 months of pregnancy, the same method is followed, except that the allowances shown under Division **1C** are to be added to the allowances for maintenance and the allowances for milk production (if the cow is still producing some milk).

Additional allowances for last 2 to 3 months of pregnancy.—For a cow during the last 2 or 3 months of pregnancy, the same method is followed, except that the allowances shown under Division **1C** are to be added to the allowances for maintenance and the allowances for milk production (if the cow is still producing some milk).

Additional allowances for milking heifers.—Heifers are still making considerable growth, and they therefore need more feed than do mature cows of the same live weights and producing the same amounts of milk. To meet their needs, the allowances stated under Division **1D** should be added to the allowances for maintenance and for milk production given in Divisions **1A** and **1B**.

These additional requirements will be met during the first lactation of heifers by feeding about 2.0 to 2.5 lbs. of additional concentrates or 3 to 4 lbs. of good hay. In their second and third lactations heifers need about half as much additional feed as this. It is especially important to feed heifers with sufficient liberality during the latter part of lactation and in the dry period.

Standards for growing dairy cattle.—The standards for growing dairy cattle provide enough nutrients for normal growth. Young cattle consuming suitable rations which contain the amounts of nu-

trients shown in the standards should reach good size for their breed.

Standards for mature dairy bulls, heavy service.—These standards provide sufficient nutrients for mature bulls used in heavy service, such as for producing semen for artificial breeding associations. A young bull that is still growing will need somewhat more nutrients than a mature bull of the same weight.

Standards for beef cattle.—The standards for wintering beef breeding cows provide sufficient nutrients to enable the cows to gain slightly in weight as pregnancy advances.

The standards for wintering beef calves and for wintering yearling cattle provide sufficient nutrients to produce approximately the rates of gain stated in the table.

The standards for growing beef cattle are intended for young cattle that are being grown rapidly throughout the entire period, and not for cattle that are "roughed through the winter," as is the common practice in most sections of the range area.

The standards for calves being fattened for baby beef are intended for calves that are placed on feed when weighing 300 to 400 lbs., and are then fattened rapidly for marketing at a weight of not over 900 to 1,000 lbs. The recommendations for fattening yearlings are for well-grown yearling cattle which weigh 600 to 750 lbs. when placed on feed, and which are marketed at about 1,100 lbs. in weight. The standards for fattening 2-year-old cattle are for cattle which weigh about 900 lbs. at the start, and are marketed at about 1,200 lbs. During the period when fattening cattle are being gotten on feed, they will consume less nutrients than shown in these standards.

The recommendations for fattening cattle are for animals that are to be fattened rapidly on a liberal amount of grain or other concentrates. Cattle fed a limited amount of concentrates will consume less total digestible nutrients (or net energy) than here shown and will not make maximum gains. (**1184–1186**)

Standards for sheep.—The amounts of nutrients advised for breeding ewes should keep them in thrifty condition.

The recommendations for growing ewe lambs and yearlings provide sufficient nutrients for normal growth.

The standards for fattening lambs are intended for fattening thrifty lambs that weigh about 50 to 65 lbs. at the start, and that are fed a sufficiently liberal amount of concentrates to make them fat at a weight of about 90 lbs. While they are being started on feed, lambs will not consume as much nutrients as shown in the standards.

Standards for horses.—The standards for horses at hard work are for horses actually doing hard work at least 7 to 8 hours a day. Horses working hard for a shorter daily period should be classed as "at medium work" or "at light work," as the case may be. The amounts of nutrients advised for idle horses should keep them in thrifty condition and should prevent loss of weight.

Standards for swine.—The standards for gilts and brood sows provide sufficient nutrients to keep them in thrifty condition.

The recommendations for growing and fattening pigs are intended for full-feeding and not for limited-feeding. Pigs of excellent breeding which are unusually growthy may consume somewhat more nutrients than shown in the standards, when self-fed an excellent ration.

Standards for poultry.—Nutrient allowances for poultry are not commonly stated in terms of digestible protein and total digestible nutrients. Feeding standards for poultry are therefore not included in this table. The nutrient allowances recently advised by a special committee of the National Research Council are given in Chapter XXXVI. (**1498, 1587, 1600**)

Table IV. Mineral Matter in Important Feeding Stuffs

Sources of data.—In order to present as accurate information as possible concerning the content of mineral nutrients in various feeding stuffs, a new compilation has been made for this twenty-second edition of *Feeds and Feeding*.

The average percentages of calcium, phosphorus, and potassium determined in this compilation are given in Appendix Table I for all feeds where sufficient data have been reported. The average amounts of certain other mineral elements in the more important feeds are shown in this table (Appendix Table IV), so far as sufficient data are available. For convenience in the use of the table, the percentages of calcium, phosphorus, and potassium in these feeds are repeated here.

The data have been compiled largely from the analyses reported by the American agricultural experiment stations and the United States Department of Agriculture. Much information has been taken from the extensive compilation of the mineral composition of crops made by Doctor K. C. Beeson of the Plant, Soil, and Nutrition Laboratory of the United States Department of Agriculture. (United States Department of Agriculture, Miscellaneous Publication 369, 1941.)

As stated in the introduction to Appendix Table I, data compiled by the Committee on Feed Composition of the National Research Council have been included in this compilation, especially data for by-product concentrate feeding stuffs. The National Research Council has recently published in preliminary form the compilation of analyses of by-product concentrates. The author has aided in this compilation by furnishing data which he has compiled.

Much less information is available concerning the percentages of mineral elements in the many different feeding stuffs than for protein, fat, fiber, nitrogen-free extract, or total mineral matter, data for which are given in Appendix Table I. Also, there is an even greater variation in the percentage of mineral nutrients in feeds of the same name than there is in the percentages of protein, fat, fiber, or nitrogen-free extract. (97, 370–372) The variation is especially great in the case of forages, including hay, pasturage and silage. For example, where the soil is very deficient in phosphorus, the phosphorus content of forages may be so low as to produce serious phosphorus deficiency, unless the lack is corrected.

The data in this table indicate the approximate average content of the various mineral nutrients in the different feeds, when crops are grown on soil which is reasonably well supplied with mineral nutrients.

The data in the table are for the various feeds as they are supplied to livestock, and not the percentages or amounts expressed on the dry matter basis. The content of each mineral is stated in terms of the mineral element, and not as the oxide, as calcium oxide (lime), potassium oxide (potash), etc.

Manganese; copper.—Because the amounts of manganese and of copper in feeds are much smaller than of the other minerals included in the table, the content of manganese and of copper is stated as milligrams per pound of feed, instead of as the percentage. A content of 4.5 milligrams per pound of feed is equivalent to one part in 100,000, or 0.001 per cent.

Cobalt; iodine.—The amounts of cobalt and of iodine in different feeds are not shown in the table, because the amounts of these minerals are highly variable. Also, too few analyses have been reported to indicate the approximate average content. The iodine content of feeds is so exceedingly small that it is measured in parts per billion, instead of in per cent. The cobalt content is also very small, most feeds having much less than one part of cobalt in ten million parts by weight, or less than 0.1 milligram per pound of feed.

The grains and their by-products have only 0.05 milligram or less of cobalt per pound. Linseed meal apparently has more cobalt than other ordinary concen-

trates, having 0.16 milligram per pound. Fish meal and tankage also may have somewhat more cobalt than the grains or their by-products. Legume forages usually have more cobalt than non-legume forages. Alfalfa hay of good quality may have 0.17 milligram per pound.

Fish meal and other sea products have much more iodine than do other common feeds. Fish meal may have 4,000 to 10,000 parts of iodine per billion. The iodine content of the cereal grains is low, ranging from an average of 57 parts per billion parts, on the dry matter basis, for oats to 177 parts per billion for corn. Most hay has slightly more iodine, and the iodine content of straw is appreciably higher.

TABLE IV. Mineral matter content

Tables V. Vitamin Content of Feeding Stuffs

Vitamin content data.—To furnish as complete information as possible concerning the vitamin content of important feeding stuffs, the following compilations of vitamin analyses have been made for this twenty-second edition of *Feeds and Feeding.*

The average values given in these tables must be considered only very approximate, because information on the amounts of vitamins in feeds is still very limited. Also, the amounts of a certain vitamin in various lots of any particular feed may vary widely. (189)

In the various divisions of the tables, a dash (—) indicates that the feed contains none or no significant amount of the vitamin. A star (*) shows that information is not available concerning the content of the vitamin. Where a value is an average of less than 5 analyses, it is printed in italics in Table V, instead of in ordinary type.

The amount of each vitamin is shown in milligrams per pound of feed as fed to livestock, and not on the dry matter basis. The amounts are thus stated (instead of in percentages), because the weights of vitamins in feeds are very small.

Sources of data.—Much of the information in these tables has been obtained from the following sources: The first is the extensive compilation of vitamin analyses by Ellis and Madsen of the United States Department of Agriculture, published in United States Department of Agriculture Mimeographed Circular 61.

The second is the compilation made by the late Frank E. James, executive secretary of the Committee on Feed Composition of the National Research Council, of which the author is a member. The author cooperated in this compilation, by furnishing data which he had compiled. This compilation was published in mimeographed form by the National Research Council in 1947, as a report of the Committee on Feed Composition.

The third is a compilation of analyses of by-product concentrate feeding stuffs, made by Donald E. Miller, technical secretary of the Committee on Feed Composition. This compilation has recently been published in preliminary form by the National Research Council. The author cooperated in this compilation by furnishing data which he had compiled largely from published reports of the state agricultural experiment stations and the United States Department of Agriculture.

Carotene, vitamin A activity, and B-complex vitamins.—The main table (Table V.) shows the approximate content of important feeds in carotene and in certain B-complex vitamins (thiamine, riboflavin, niacin, and pantothenic acid), so far as data are available.

Since the carotene content in feeds of the same name varies so widely, especially in the case of roughages, the following summary by Guilbert of the California Station is very helpful. (National Research Council, Recommended Nutrient Allowances for Beef Cattle, 1945.) This indicates the common range in carotene content in various types of feeds.

Range in carotene content of various types of feeds

	Carotene Mg. per lb.
Fresh green legumes and grasses, immature	15 to 40
Alfalfa meal, dehydrated, fresh, dehydrated without field curing, very bright green color	110 to 135
Alfalfa meal, dehydrated, after considerable time in storage, bright green color	50 to 70
Alfalfa leaf meal, bright green color	60 to 80
Legume hays, including alfalfa, very quickly cured with minimum sun exposure, bright green color, leafy	35 to 40
Legume hays, including alfalfa, good green color, leafy	18 to 27
Legume hays, including alfalfa, partly bleached, moderate amount of green color	9 to 14

Range in carotene content of various types of feeds—continued.

	Carotene Mg. per lb.
Legume hays, including alfalfa, badly bleached or discolored, traces of green color	4 to 8
Nonlegume hays, including timothy, cereal, and prairie hays, well cured, good green color	9 to 14
Nonlegume hays, average quality, bleached, some green color	4 to 8
Legume silage	5 to 20
Corn and sorghum silages, medium to good green color	2 to 10
Grains, mill feeds, protein concentrates, and by-product concentrates, except yellow corn and its by-products	0.01 to 0.2

In addition to the amounts of carotene given in the first column of figures in the main table which follows immediately, the second column states the approximate vitamin A activity, measured in International Units of vitamin A. These values have been computed on the assumption that 0.6 microgram (0.0006 milligram) of carotene is equivalent to 1 International Unit of vitamin. As has been shown previously, this is the approximate relative value of carotene and vitamin A for poultry and for rats. (**193, 1517**) For cattle, sheep, horses, and swine, the relative vitamin A value of carotene is much less than this.

Other B-complex vitamins.—But little information is available concerning the amounts in feeds of the other B-complex vitamins which are not included in the main table. The approximate amounts of biotin, choline, folic acid, and pyridoxine in some important feeds are shown in Table Va. Since betaine can partially replace choline in function, the amounts of betaine in certain feeds are also stated in this table. (**218**)

Table Vb shows the approximate content of vitamin B_{12} in the few feeds in which the content has been determined.

Vitamin D and Vitamin E.—Very little information has been obtained concerning the amounts of these vitamins in various feeds. The available data are given in Tables Vc and Vd. The general information about the content of these vitamins is summarized in Chapter VII. (**204–205, 223**)

TABLE V. Vitamin content of feeding stuffs

Feeding stuff	Carotene	Vitamin A activity	Thiamine	Riboflavin	Niacin	Pantothenic acid

TABLE Vb. Vitamin B_{12} content of certain feeding stuffs

It is generally believed that feeds of plant origin have no appreciable amounts of vitamin B_{12} or of other substances having vitamin B_{12} activity.

However, certain feeds of plant origin, including some green forages, dehydrated alfalfa or other dehydrated forage, and some hays, may show an apparent small content of vitamin B_{12} by microbiological methods of analysis.

The approximate vitamin B_{12} contents of certain feeds of animal origin and of certain fermentation by-products are shown in the following table. The amounts of vitamin B_{12}, even in these feeds, are so exceedingly small that the content is stated in terms of micrograms per pound of feed, instead of milligrams. (1,000 micrograms equal 1 milligram.)

Vitamin B_{12} content of certain feeds

Feeding stuff	Vitamin B_{12} per lb. of feed	Feeding stuff	Vitamin B_{12} per lb. of feed
	Micrograms		Micrograms
Buttermilk, dried	9	Fish solubles, cond., redfish	208
Cod-liver oil meal	0.4	Fish solubles, cond., sardine	472
Crab meal	192	Fish solubles, cond., tuna	219
Distillers solubles, dried	13	Liver meal, animal	246
Feather meal, hydrolyzed	39	Meat scrap	31
Fish meal, all analyses	87	Meat and bone scrap	57
Fish meal, herring	107	Milk, cow's	2
Fish meal, menhaden	84	Poultry by-product meal	129
Fish meal, redfish	65	Sewage sludge, dried	817
Fish meal, salmon	41	Skimmilk, dried	25
Fish meal, sardine	85	Whale meat meal	40
Fish meal, tuna	65	Whey, dried	11
Fish meal, white fish	45	Yeast, dried	3
Fish solubles, condensed, all analyses	305	Yeast, molasses distillers, dried	4
Fish solubles, cond., herring	259		

TABLE Vc. Vitamin D content of certain feeding stuffs

Feeding stuff	Vitamin D content in International Units per lb.
Dry Roughages	
Alfalfa hay, field-cured	905
Alfalfa hay, barn-dried	215
Alfalfa, dehydrated	66
Alfalfa leaves, from field-cured hay	4,740
Alfalfa stems, from field-cured hay	780
Clover hay, field-cured	868
Clover hay, barn-dried	195
Mixed grass and legume hay, field-cured	523
Mixed grass and legume hay, barn-dried	448
Mixed grass and legume hay, dehydrated	391

Clover, white	45.4	Wheat shorts	14.4
Orchard grass	49.4		
Soybean forage	31.8		

TABLE VI. WEIGHTS OF CONCENTRATES AND OTHER FEEDS

In computing rations for farm animals it is desirable to know the weight per quart, or the bulk, of the different concentrates. The following table, compiled chiefly from *Massachusetts Bulletin 136* by Smith and Perkins, *Louisiana Bulletin 114* by Halligan, and *Indiana Bulletin 141* by Jones, Haworth, Cutler, and Summers is therefore presented.

Feeding stuff	One quart weighs	One pound measures	Feeding stuff	One quart weighs	One pound measures
Concentrates	Lbs.	Qts.	**Concentrates—Cont.**	Lbs.	Qts.
Barley, whole	1.5	0.7	Molasses feeds	0.8	1.3
Barley, ground	1.1	0.9	Oats	1.0	1.0
Beans, field	1.7	0.6	Oats, ground	0.7	1.4
Beet pulp, dried	0.6	1.7	Oatmeal, without hulls	1.7	0.6
Brewers' grains, dried	0.6	1.7	Oat middlings	1.5	0.7
Buckwheat, whole	1.4	0.7	Oat mill feed	0.8	1.3
Buckwheat feed	0.6	1.7	Peas, field	2.1	0.5
Buckwheat flour	1.6	0.6	Rice bran	0.8	1.3

Flaxseed	1.6	0.6	Wheat screenings	1.0	1.0
Flaxseed screenings	1.1	0.9	Wheat standard middlings	0.8	1.3
Hominy feed	1.1	0.9			
Linseed meal, old process	1.1	0.9	**Roughages**		
Linseed meal, new process	0.9	1.1	Alfalfa meal	0.6	1.7
Malt sprouts	0.6	1.7	Buckwheat hulls	0.5	2.0
Millet seed, foxtail	1.6	0.6	Cottonseed hulls	0.3	3.3
Molasses, cane	3.0	0.3	Oat hulls	0.4	2.5

Table VII. Example Rations for Farm Animals

Using the example rations.—The following examples of balanced rations for the different classes of stock are presented as guides in selecting efficient balanced rations adapted to various conditions. In using these suggestions, one should not limit his choice to the particular combinations of feeds here given. Instead, he should determine whether or not modifications can be made in these rations which will make them more economical under his local conditions. One can readily find which of various available feeds are actually the cheapest by using the method explained in Chapter XII.

Unless otherwise indicated, the amounts of feed shown in the tables are the amounts to be fed per head daily. For animals of different sizes than stated in the tables, the amounts of feed should be increased or decreased in accordance with the amounts of nutrients recommended in Appendix Table III for animals of the particular size.

Making changes in the rations.—The following will indicate the changes that may be made in these rations:

Other grains can be substituted for the grains included in an example ration. If the grain substituted is higher or lower in protein than the grain which it replaces, the amount of protein supplement in the ration should be changed to provide approximately the same percentage of protein in the ration.

For example, ground corn can be replaced by hominy feed, corn feed meal, ground grain sorghum, ground barley, or ground wheat. When barley or wheat is fed in place of corn, the amount of protein supplement may be reduced somewhat. Also, a little less supplement is needed with grain sorghums than with corn.

Where oats are included in a concentrate mixture to provide bulk, they can be replaced by dried beet pulp. More protein supplement will then be needed because of the lower protein content of dried beet pulp.

Instead of the protein supplements used in the various example rations, other supplements can be substituted, such as brewers' dried grains, distillers dried grains, corn gluten meal, and peanut oil meal. If the percentage of protein differs appreciably from that in the supplement used in the example ration, the amount should be changed accordingly. In making any substitution of protein supplements in a ration for swine or poultry, one must be sure that the ration will furnish protein of proper quality. (**1385–1386, 1500–1501**)

The proportions of protein supplements in the example rations are based on the most common grades of the various supplements. For example, the computations have been based on cottonseed meal of 41 per cent protein grade; linseed meal, expeller or hydraulic process, 34 per cent protein guarantee; and soybean oil meal, solvent process, 44 per cent protein guarantee. If the protein supplement used has a decidedly higher or lower protein content than stated, the amount of supplement needed will be altered correspondingly.

Dairy Cattle

Concentrate or "grain" mixtures for dairy cows and heifers

A. Mixtures containing approximately 12 per cent protein

For cows in milk which are fed good alfalfa, soybean, or cowpea hay (at least 1 lb. daily per 100 lbs. live weight) with corn silage, sorghum silage, corn fodder, sorghum, fodder, or roots. When alfalfa, soybean, or cowpea hay is fed as the only roughage, merely a mixture of farm grain supplies sufficient protein for all except unusually high-producing cows.

For cows in milk which are fed red clover hay as the only roughage.

For cows in milk which are on excellent pasture.

For dry cows, when at least one-third the roughage (on the dry basis) is legumes. Other mixtures for fitting dry cows are given in **Division B.**

For heifers over 6 months old, when

one-half the roughage (on the dry basis) is alfalfa, soybean, or cowpea hay.

1. Ground corn	1,160 lbs.
Ground oats	500 lbs.
Wheat bran	220 lbs.
Soybean oil meal (or cottonseed meal)	100 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 9.8%
Total dig. nutrients, 75.3%

2. Ground corn	1,130 lbs.
Ground oats	500 lbs.
Wheat bran	200 lbs.
Linseed meal	150 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 9.8%
Total dig. nutrients, 75.1%

3. Ground barley (or wheat)	1,030 lbs.
Ground oats	700 lbs.
Wheat bran	250 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 10.1%
Total dig. nutrients, 72.91%

4. Ground corn	1,000 lbs.
Ground oats	640 lbs.
Wheat bran	200 lbs.
Corn gluten feed	70 lbs.
Soybean oil meal	70 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 9.8%
Total dig. nutrients, 74.5%

5. Ground grain sorghum	1,400 lbs.
Ground oats	330 lbs.
Wheat bran	200 lbs.
Cottonseed meal (or soybean oil meal)	50 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 9.6%
Total dig. nutrients, 76.0%

6. Corn-and-cob meal	1,310 lbs.
Wheat bran	500 lbs.
Cottonseed meal (or soybean oil meal)	85 lbs.
Linseed meal	85 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 9.6%
Total dig. nutrients, 70.9%

B. Mixtures for fitting dry cows and for freshening cows

Mixture No. 1, which contains somewhat more than 12 per cent total protein, is suitable for use when at least one-third of the roughage, on the dry basis, is legume forage. When little or no legume roughage is available, such a mixture as No. 2, which contains 16 per cent protein, is preferable.

1. Ground corn	760 lbs.
Ground oats	600 lbs.
Wheat bran	500 lbs.
Linseed meal	100 lbs.
Bone meal (or other safe supplement)	20 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 10.2%
Total dig. nutrients, 72.0%

2. Ground corn	590 lbs.
Ground oats	500 lbs.
Wheat bran	500 lbs.
Linseed meal	360 lbs.
Bone meal (or other safe supplement)	20 lbs.
Ground limestone	10 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 13.1%
Total dig. nutrients, 71.4%

C. Mixtures containing approximately 14 per cent protein

For cows in milk which are fed red clover hay (at least 1 lb. daily per 100 lbs. live weight) and corn or sorghum silage or corn or sorghum fodder, when protein supplements are expensive.

For cows in milk which are on very good pasture.

For dry cows when only one-fourth of the roughage (on the dry basis) is legume.

For heifers over 6 months old, when one-half the roughage (on the dry basis) is clover hay.

1. Ground corn	1,055 lbs.
Ground oats	500 lbs.
Wheat bran	200 lbs.
Soybean oil meal (or cottonseed meal)	225 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Total dig. nutrients, 74.7%

5. Ground grain sorghum ...... 1,275 lbs.
Ground oats .... 330 lbs.
Wheat bran .... 200 lbs.
Cottonseed meal (or soybean oil meal) .... 175 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 11.1%
Total dig. nutrients, 75.5%

6. Corn-and-cob meal .... 1,220 lbs.
Wheat bran .... 450 lbs.
Cottonseed meal (or soybean oil meal) .... 155 lbs.
Linseed meal .... 155 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 11.2%
Total dig. nutrients, 71.1%

D. Mixtures containing approximately 16 per cent protein

For cows in milk which are fed good red clover or alsike clover hay (at least 1 lb. daily per 100 lbs. live weight) with corn silage, sorghum silage, corn fodder, sorghum fodder, or roots.

For cows in milk which are fed good mixed clover-and-grass hay (containing at least 30 per cent clover) and corn or sorghum silage or corn or sorghum fodder, when protein supplements are unusually expensive.

For cows in milk which are on good pasture.

For dry cows which are fed little or no legume roughage.

1. Ground corn .... 945 lbs.
Ground oats .... 500 lbs.
Wheat bran .... 200 lbs.
Soybean oil meal (or cottonseed meal) .... 335 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 13.9%
Total dig. nutrients, 75.1%

2. Ground barley .... 1,000 lbs.
Ground oats .... 560 lbs.
Wheat bran .... 200 lbs.
Soybean oil meal (or cottonseed meal) .... 220 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 13.6%
Total dig. nutrients, 73.8%

3. Ground corn .... 830 lbs.
Ground oats .... 500 lbs.
Wheat bran .... 200 lbs.
Corn gluten feed .... 225 lbs.
Soybean oil meal (or cottonseed meal) .... 225 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 13.6%
Total dig. nutrients, 74.6%

4. Ground corn .... 820 lbs.
Ground oats .... 500 lbs.
Wheat bran .... 220 lbs.
Linseed meal .... 440 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 13.3%
Total dig. nutrients, 74.3%

5. Ground grain sorghum ...... 1,180 lbs.
Ground oats .... 300 lbs.
Wheat bran .... 200 lbs.
Cottonseed meal (or soybean oil meal) .... 300 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 12.7%
Total dig. nutrients, 75.1%

6. Corn-and-cob meal .... 1,090 lbs.
Wheat bran .... 450 lbs.
Cottonseed meal (or soybean oil meal) .... 220 lbs.
Linseed meal .... 220 lbs.
Salt .... 20 lbs.
Total .... 2,000 lbs.
Dig. protein, 13.0%
Total dig. nutrients, 71.1%

E. Mixtures containing approximately 18 per cent protein

For cows in milk which are fed mixed clover-and-timothy hay or other mixed clover-and-grass hay containing at least 30 per cent clover (at least 1 lb. of hay daily per 100 lbs. live weight), this hay being fed with corn or sorghum silage, corn or sorghum fodder, or roots.

For cows in milk which are on fair pasture.

For heifers over 6 months old, when only about one-fourth the roughage (on the dry basis) is legume.

1. Ground corn	685 lbs.
Ground oats	500 lbs.
Wheat bran	200 lbs.
Soybean oil meal	270 lbs.
Distillers dried corn grains	325 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 14.7%
Total dig. nutrients, 75.8%

2. Ground barley	940 lbs.
Ground oats	500 lbs.
Wheat bran	200 lbs.
Soybean oil meal (or cottonseed meal)	340 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 15.5%
Total dig. nutrients, 74.0%

3. Ground corn	680 lbs.
Ground oats	500 lbs.
Wheat bran	200 lbs.
Corn gluten feed	300 lbs.
Soybean oil meal (or cottonseed meal)	300 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 15.5%
Total dig. nutrients, 74.3%

4. Ground corn	540 lbs.
Ground oats	500 lbs.
Wheat bran	200 lbs.
Linseed meal	370 lbs.
Corn gluten feed	370 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 15.1%
Total dig. nutrients, 73.5%

5. Ground grain sorghum	1,045 lbs.
Ground oats	300 lbs.
Wheat bran	200 lbs.
Cottonseed meal (or soybean oil meal)	435 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 14.4%
Total dig. nutrients, 74.5%

6. Corn-and-cob meal	970 lbs.
Wheat bran	450 lbs.
Cottonseed meal (or soybean oil meal)	280 lbs.
Linseed meal	280 lbs.
Salt	20 lbs.
Total	2,000 lbs.

Dig. protein, 14.5%
Total dig. nutrients, 71.1%

F. Mixtures containing approximately 20 per cent protein (Add 20 lbs. ground limestone per ton if roughage is grown on soil very deficient in calcium.)

For cows in milk which are fed mixed legume-and-grass hay containing less than 30 per cent legumes, this hay being fed with corn or sorghum silage, corn or sorghum fodder, or roots.

For cows in milk which are fed non-legume roughage of good quality and which are producing sufficient milk so that they require at least 8 to 10 lbs. of concentrate or grain mixture.

For cows in milk which are on poor pasture.

For heifers over 6 months old which are fed no legume roughage.

1. Ground corn	630 lbs.
Ground oats	400 lbs.
Wheat bran	200 lbs.
Soybean oil meal	370 lbs.
Distillers dried corn grains	380 lbs.

Beef Cattle

Wintering mature beef breeding cows in calf, weight 1,000 lbs.

1. Legume hay or mixed legume-and-grass hay of good quality, 16 to 25 lbs.
2. Legume hay, 5 to 10 lbs.; cereal straw, 10 to 15 lbs.
3. Corn silage or sorghum silage, 50 to 60 lbs.; cottonseed meal, soybean oil meal, linseed meal, or other high-protein supplement, 1 lb.; ground limestone, 0.1 lb.
4. Corn silage or sorghum silage, 25 to 40 lbs.; legume hay, 5 to 7 lbs.
5. Cereal straw, full-fed; linseed meal, cottonseed meal, soybean oil meal, or other high-protein supplement, 1 lb.; ground limestone, 0.1 lb.
6. Prairie hay or other grass hay, full-fed (16 to 25 lbs.); plus 0.5 to 0.75 lb. high-protein supplement unless hay is early-cut. It is advisable to add 0.1 lb. ground limestone if hay is grown on soil deficient in calcium.

Wintering beef calves to gain 0.75 to 1.00 lb. per head daily

If a gain of much more than 1.00 lb. per head daily is desired, it will usually be necessary to add 2 lbs. or more of grain to these rations.

1. Legume hay or mixed hay containing at least one-half legumes, 12 to 15 lbs.
2. Corn silage or sorghum silage, 25 to 35 lbs.; soybean oil meal, cottonseed meal, linseed meal, or other high-protein supplement, 1 lb.; ground limestone, 0.1 lb. unless silage is raised on soil well supplied with calcium.
3. Corn silage or sorghum silage, 20 to 30 lbs.; legume hay, 3 to 4 lbs.
4. Prairie hay, other grass hay, or corn or sorghum fodder, 10 to 14 lbs.; cottonseed meal, soybean oil meal, or other high-protein supplement, 0.75 to 1.00 lb.; ground limestone, 0.1 lb. unless roughage is raised on soil well supplied with calcium.
5. Prairie hay, other grass hay, or corn or sorghum fodder, 8 to 12 lbs.; ground barley, oats, grain sorghum, or wheat, 2 lbs.; ground limestone, 0.1 lb. unless roughage is raised on soil well supplied with calcium.

Wintering beef yearlings

In general the same types of rations are satisfactory as have been suggested for wintering beef calves, except that greater amounts of feed are required and some of the roughage may consist of such cheap feeds as corn or sorghum stover, or cereal straw.

Calves being fattened for baby beef, average weight 600 lbs.

1. Corn or sorghum silage, 10 lbs. or more; alfalfa or other legume hay, 2 lbs. or more; corn or ground grain sorghum, 10 lbs.; soybean oil meal, linseed meal, cottonseed meal, or other high-protein supplement, 1.25 to 1.5 lbs.
2. Alfalfa, soybean, or cowpea hay, 4 to 5 lbs.; corn or grain sorghum, 11 lbs.; cottonseed meal, linseed meal, or other high-protein supplement, 0.50 to 0.75 lb. If 6 lbs. or more of legume hay of good quality are fed, no protein supplement is needed.
3. Alfalfa, soybean, or cowpea hay, 4 to 5 lbs.; ground barley, wheat, or oats, 12 lbs.
4. Red clover hay, 4 to 5 lbs.; corn or ground grain sorghum, 11 lbs.; soybean oil meal, linseed meal, cottonseed meal, or other high-protein supplement, 1.0 to 1.25 lbs.
5. Clover-and-timothy hay (containing 30 per cent or more clover), 4 to 5 lbs.; corn or ground grain sorghum, 11 lbs.; cottonseed meal, soybean oil meal, or other high-protein supplement, 1.5 lbs.
6. Corn or sorghum silage, 16 lbs.; corn or ground grain sorghum, 10 lbs.; cottonseed meal, soybean oil meal, linseed meal, or other high-protein supplement, 1.5 to 2 lbs.; ground limestone, 0.1 lb.
7. Cottonseed hulls, 4 lbs.; cowpea hay, 2 lbs.; corn or ground grain sorghum, 10 lbs.; cottonseed meal or other high-protein supplement, 1.5 lbs.

Fattening yearling cattle, average weight 900 lbs.

1. Corn or sorghum silage, 15 lbs.; alfalfa or other legume hay, 3 lbs.; corn or ground grain sorghum, 13 lbs.; linseed meal, cottonseed meal, or other high-protein supplement, 1 lb.
2. Alfalfa, soybean, or cowpea hay, 6 to 8 lbs.; corn or other grain, 14 lbs.
3. Red clover hay, 6 to 8 lbs.; corn or ground grain sorghum, 13.5 lbs.; cottonseed meal, soybean oil meal, or other high-protein supplement, 0.5 lb.
4. Red clover hay, 6 to 8 lbs.; ground barley, wheat, or oats, 14 lbs.
5. Clover-and-timothy hay (containing 30 per cent or more clover), 6 to 8 lbs.; corn or ground grain sorghum, 13 lbs.; soybean oil meal, linseed meal, cottonseed meal, or other high-protein supplement, 1 to 1.25 lbs.
6. Corn or sorghum silage, 20 lbs.; corn or ground grain sorghum, 13 lbs.; high-protein supplement, 1.5 to 1.75 lbs.; ground limestone, 0.1 lb.
7. Cottonseed hulls, 6 lbs.; cowpea hay, 2 lbs. or more; corn or ground grain sorghum, 13 lbs.; cottonseed meal or other high-protein supplement, 1.5 lbs.

Fattening 2-year-old cattle, weight 1,000 lbs.

1. Corn or sorghum silage, 25 lbs.; alfalfa, soybean, or cowpea hay, 4 lbs.; corn or ground grain sorghum, 14 lbs. Adding 0.5 lb. high-protein supplement will increase the rate of gain slightly and may be profitable. The supplement should be added if less legume is fed.
2. Corn or sorghum silage, 25 lbs.; red clover hay, 4 lbs.; corn or ground grain sorghum, 14 lbs.; linseed meal, cottonseed meal, or other high-protein supplement, 1.0 lb.
3. Alfalfa, soybean, or cowpea hay, 10 lbs.; corn or other grain, 15 lbs.
4. Red clover hay, 10 lbs.; corn or ground grain sorghum, 14.5 lbs.; cottonseed meal or other high-protein supplement, 0.5 lb.
5. Clover-and-timothy hay (containing 30 per cent or more clover), 10 lbs.; corn or ground grain sorghum, 14 lbs.; soybean oil meal or other high-protein supplement, 1.0 lb.
6. Corn or sorghum silage, 30 lbs.; corn or ground grain sorghum, 14 lbs.; linseed meal or other high-protein supplement, 1.5 lbs.; ground limestone, 0.1 lb.
7. Cottonseed hulls, 7 lbs.; cowpea hay, 3 lbs.; corn or ground grain sorghum, 14 lbs.; cottonseed meal or other high-protein supplement, 1.5 lbs.

Sheep

Wintering pregnant ewes up to 4 to 6 weeks before lambing, weight 120 lbs.

1. Good-quality legume hay or mixed legume-and-grass hay containing 50 per cent legumes, 3.6 to 4.5 lbs.
2. Legume hay, 2.6 to 3.3 lbs.; corn or sorghum silage, 2.0 to 3.0 lbs.
3. Corn fodder, sorghum fodder, corn stover, sorghum stover, or cereal straw, full-fed (1.0 to 2.0 lbs.); legume hay, 2.0 lbs. It may be necessary to add 0.25 to 0.50 lb. grain to this ration to keep the ewes in the desired condition.
4. Roots, 2.0 to 3.0 lbs.; legume hay, 3.1 to 3.6 lbs.
5. Early-cut, well-cured grass hay, 1.8 to 2.3 lbs.; legume hay, 1.8 to 2.3 lbs.
6. Early-cut grass hay, 2.3 to 3.0 lbs.; corn or sorghum silage, 2.0 to 3.0 lbs.; 0.25 lb. linseed meal or other high-protein supplement; 0.25 ounce ground limestone per head daily.

Wintering pregnant ewes during 4 to 6 weeks before lambing

To one of the preceding roughage allowances, add 0.5 lb. per head daily (or more if necessary) of one of the concentrate mixtures listed later.

Ewes not on pasture nursing lambs

To one of the preceding roughage allowances, add 1.0 lb. or slightly more of one of the following concentrate mixtures:

Concentrate or grain mixtures for ewes

These concentrate mixtures are suitable for ewes which are nursing lambs or for pregnant ewes.

A. For feeding when at least one-half the roughage (on the dry basis) is actually good legume roughage.

1. Oats, 67 lbs.; wheat bran, 33 lbs.
2. Corn or other grain, 50 lbs.; oats, 20 lbs.; wheat bran, 20 lbs.; linseed meal, 10 lbs.
3. Corn, 80 lbs.; linseed meal, 20 lbs.
4. Oats, 50 lbs.; corn, 50 lbs. This mixture is slightly too low in protein to use for ewes nursing lambs unless nearly all of the roughage is legume forage.
5. A good mixed dairy feed containing 12 to 14 per cent total protein.

B. For feeding when only a small part or none of the roughage is legume

(When fed such roughage, ewes nursing lambs should receive 1.25 lbs. per head daily of concentrate mixture.)

1. Oats, 30 lbs.; corn or other grain, 20 lbs.; wheat bran, 30 lbs.; linseed meal or other high-protein supplement, 20 lbs.
2. Oats, 60 lbs.; wheat bran, 25 lbs.; linseed meal or other high-protein supplement, 15 lbs.
3. A good mixed dairy feed containing 16 to 18 per cent total protein.

Fattening lambs on full feed, weight 70 lbs.

1. Legume hay, 1.4 lbs.; corn or grain sorghum, 1.5 lbs. The addition of 0.1 lb. high-protein supplement will increase the gains a trifle, but will usually not be profitable.
2. Legume hay, 1.4 lbs.; barley, wheat, or oats, 1.5 lbs.
3. Corn or sorghum silage, 1.75 lbs.; legume hay, 0.75 lb.; corn or other grain, 1.5 lbs.; linseed meal, cottonseed meal, or other high-protein supplement, 0.10 lb. Lambs will make satisfactory gains without the supplement, if at least this much good legume hay is fed. However, unless supplements are unusually high in price, it will generally pay to add the supplement.
4. Corn or sorghum silage, 3.0 to 4.0 lbs.; corn or other grain, 1.5 lbs.; cottonseed meal, linseed meal, soybean oil meal, or other high-protein supplement, 0.20 to 0.30 lb.; ground limestone, 0.25 ounce.
5. Mixed clover-and-grass hay, 1.4 lbs.; corn, 1.5 lbs.; linseed meal, 0.10 to 0.15 lb.
6. Cottonseed hulls, 1.0 lb.; cowpea hay, 0.50 lb.; corn or other grain, 1.5 lbs.; cottonseed meal or other high-protein supplement, 0.15 to 0.20 lb.

Horses and Mules

Horses and mules at hard work, weight 1,200 lbs.

1. Grass hay, 12 lbs.; oats, 16 lbs.
2. Grass hay, 12 lbs.; corn, 13 lbs.; linseed meal or other high-protein supplement, 1 lb.
3. Legume hay, 12 lbs.; corn, 13.5 lbs.
4. Legume hay, 6 lbs.; grass hay, 6 lbs.; corn, 14 lbs.
5. Shredded corn fodder, 6 lbs.; legume hay, 6 lbs.; oats, 15 lbs.
6. Oats or barley straw, chopped, 4 lbs.; legume hay, 8 lbs.; oats, 16 lbs.

Horses and mules at medium work, weight 1,200 lbs.

1. Grass hay, 14 lbs.; oats, 11 lbs.
2. Grass hay, 14 lbs.; corn, 9 lbs.; linseed meal or other high-protein supplement, 0.75 lb.
3. Legume hay, 14 lbs.; corn, 9 lbs.
4. Legume hay, 7 lbs.; grass hay, 7 lbs.; corn, 9.5 lbs.
5. Shredded corn fodder, 7 lbs.; legume hay, 7 lbs.; oats, 10 lbs.
6. Oat or barley straw, chopped, 5 lbs.; legume hay, 9 lbs.; oats, 11 lbs.

Horses and mules at light work, weight 1,200 lbs.

1. Grass hay, 16 lbs.; oats, 6 lbs.
2. Grass hay, 16 lbs.; corn, 4.5 lbs.; linseed meal or other high-protein supplement, 0.5 lb.
3. Legume hay, 16 lbs.; corn, 4 lbs.
4. Legume hay, 8 lbs.; grass hay, 8 lbs.; corn, 4.5 lbs.
5. Shredded corn fodder, 8 lbs.; legume hay, 8 lbs.; oats, 5 lbs.
6. Oat or barley straw, chopped, 6 lbs.; legume hay, 10 lbs.; oats, 6 lbs.

Idle horses and mules, live weight 1,200 lbs.

1. Grass hay, 17.5 lbs.; linseed meal or other high-protein supplement, 0.75 lb.
2. Legume hay, 17 lbs.
3. Legume hay, 9 lbs.; grass hay, 9 lbs.
4. Corn or sorghum stover, 11 lbs.; legume hay, 8 lbs.
5. Corn or sorghum silage, 15 lbs.; oat or barley straw, 6 lbs.; legume hay, 7 lbs.
6. Oat or barley straw, 6 lbs.; legume hay, 12 lbs.

Brood mares nursing foals, but not at work, live weight 1,200 lbs.

1. Alfalfa, soybean, or cowpea hay, 16 lbs.; corn or other grain, 6 lbs.
2. Red clover hay, 16 lbs.; oats or ground barley, 3 lbs.; corn, 3 lbs.
3. Mixed clover-and-timothy hay (containing 30 per cent or more clover), 16 lbs.; oats, 6 lbs.
4. Timothy or other grass hay, 16 lbs.; oats, 3 lbs.; bran, 3 lbs.; linseed meal or other high-protein supplement, 1 lb.

Swine

Except where indicated, the amounts of feed stated are the amounts in each 100 lbs. of concentrate mixture, and not the amounts eaten per head daily.

Salt should be supplied, free-choice, in addition to these rations, or else 0.5 lb. of salt should be added to each 100 lbs. of the feed mixture. In areas where there is likelihood of a trace-mineral deficiency, trace-mineralized salt should be used instead of ordinary salt, or a mineral supplement containing trace minerals should be provided, free-choice.

Brood sows, gilts, and boars

An excellent ration for pregnant brood sows and gilts is merely sufficient corn or other grain, with choice legume hay fed in a rack, and either 0.25 to 0.35 lb. per head daily of tankage, meat scraps, or fish meal, or else 4 to 5 lbs. skimmilk or buttermilk per head daily.

The following mixtures are also excellent for brood sows, gilts, and boars. The first of the following tables gives mixtures which are well adapted for feeding in dry lot, without pasture, to pregnant gilts, to suckling sows of all ages, and to boars.

The second table gives mixtures for feeding in dry lot, without pasture, to pregnant sows which are a year or more old. Such sows need less protein than pregnant gilts or than sows which are nursing litters.

If desired, the proportion of legume hay in a mixture for pregnant sows and for boars may be increased to 20 lbs. per 100 lbs. of mixture. On the other hand, for sows that are nursing litters, it may be wise to reduce the proportion of legume hay to 5 or 10 lbs. per 100 lbs. of mixture.

The third table gives in separate divisions suitable mixtures for feeding on good pasture to pregnant gilts and then mixtures for feeding to pregnant sows that are a year old or older.

Mixtures for pregnant gilts and suckling sows of all ages—not on pasture

Pig pre-starters for early-weaned pigs

1. Rolled oats or oat groats, 1,050 lbs.; molasses, 200 lbs.; sugar, 200 lbs.; soybean oil meal, 400 lbs.; dried skimmilk, 100 lbs.; phosphorus supplement, 20 lbs.; ground limestone, 20 lbs.; trace-mineralized salt, or salt plus a trace-mineral mixture, 10 lbs.; plus vitamin and antibiotic pre-mix, supplying vitamins A, D, riboflavin, niacin, calcium pantothenate, choline, vitamin B_{12}, and an effective antibiotic; total 2,000 lbs. (Ill. Cir. 719.)
2. Yellow corn, fine-ground, 235 lbs.; sugar, cane or beet, 200 lbs.; dextrose (corn sugar), 100 lbs.; oat groats, finely-ground, 100 lbs.; dried skimmilk, spray-dried, low heat, 800 lbs.; dried whey, 200 lbs.; soybean oil meal, solvent, 50% protein, re-ground fine, 100 lbs.; stabilized lard, 100 lbs.; condensed fish solubles, 50 lbs.; dicalcium phosphate, 11 lbs.; calcium carbonate, 3 lbs.; iodized salt, 10 lbs.; trace-mineral mixture, 4 lbs.; corn steep water, dried, 20 lbs.; brewers' dried yeast, 20 lbs.; dried beet pulp, 40 lbs.; vitamin, antibiotic, and arsonic supplement pre-mix, 7 lbs., supplying the vitamins stated in the preceding formula and also niacin, thiamine, pantothenic acid, choline, pyridoxine, folic acid, para-amino-benzoic acid, ascorbic acid, vitamin E, and vi-

tamin K, 7 lbs.; total, 2,000 lbs. (Iowa Station, mimeo. rpt.)

3. Yellow corn, fine-ground, 300 lbs.; sugar, cane or beet, 300 lbs.; dextrose (corn sugar), 100 lbs.; oat groats, finely-ground, 100 lbs.; dried whey, 300 lbs.; soybean oil meal, solvent, 50% protein, re-ground fine, 600 lbs.; stabilized lard, 100 lbs.; condensed fish solubles, 50 lbs.; dicalcium phosphate, 34 lbs.; calcium carbonate, 9 lbs.; iodized salt, 10 lbs.; trace-mineral mixture, 4 lbs.; corn steep water, dried, 20.5 lbs.; brewers' dried yeast, 20 lbs.; dried beet pulp, 40 lbs.; methionine, 0.5 lb.; vitamin, antibiotic, and arsonic supplement premix as in preceding formula, 7 lbs.; pepsin (proteolytic enzyme, 1:3,000), 5 lbs.; total, 2,000 lbs. (Iowa Station, mimeo. rpt.)

Pig starters, or mixtures for creep-feeding suckling pigs

1. For pigs on good pasture a simple ration is excellent, such as self-fed, free-choice, yellow corn (coarsely ground or shelled) or else hulled oats or rolled oats, or a mixture of corn and oats, with one of the protein supplemental mixtures advised in Chapter XXXIV for pasture feeding, also self-fed free-choice. (**1422**)
2. For pigs in dry lot. Ground yellow corn, 80 lbs.; soybean oil meal, 12 lbs.; fish meal, 1 lb.; meat scrap, 3 lbs.; dehydrated alfalfa meal, 2–4 lbs.; mineral mixture (equal parts phosphorus supplement, ground limestone, and trace-mineralized salt), 1.5 lbs.; antibiotic-vitamin B_{12} feed supplement, 0.5 lb.; vitamin A-D supplement, 0.1 lb.
3. For pigs in dry lot. Ground yellow corn, 46 lbs.; ground oat groats, 30 lbs.; soybean oil meal, 18 lbs.; dried skimmilk, 5 lbs.; plus vitamin, antibiotic, and mineral supplements as in preceding ration.
4. For pigs in dry lot. Ground yellow corn, ground grain sorghum, or ground wheat, 34 lbs.; rolled oats or ground oat groats, 30 lbs.; soybean oil meal, 5.5 lbs.; meat scrap, 5 lbs.; fish meal, 5 lbs.; dried skimmilk, 10 lbs.; sugar, cane or glucose, 10 lbs.; iodized salt, 0.5 lb.; plus vitamin and antibiotic supplements.

Growing and fattening pigs

In addition to these rations, salt should be supplied in a suitable mineral box or feeder, or 0.5 lb. of salt should be mixed with each 100 lbs. of the entire ration. Also, except where a phosphorus supplement or ground limestone is included in the mixture, it is advisable to provide a suitable calcium-phosphorus mineral mixture separately.

An antibiotic-vitamin B_{12} feed supplement should be added to rations for growing and fattening pigs not on excellent pasture.

Where a mixture of grain and protein supplements is fed, the grain should be ground. Legume hay should be ground or chopped very finely for use in a feed mixture.

In these rations other plant-protein supplements can be substituted for soybean oil meal or linseed meal, when used as advised in the discussions of the various supplements in Part II. Another plant-protein supplement should be substituted for all or part of the soybean oil meal only when the quality of protein in the ration will still be satisfactory.

A. Supplemental mixtures for self-feeding, free-choice, to pigs not on pasture, in addition to corn or grain sorghum, also self-fed, free-choice

As is stated in Chapter XXXVI, when such supplemental mixtures are self-fed, free-choice, with barley, wheat, oats, or rye, which are all higher in protein than corn or grain sorghum, the pigs may eat more of the supplement than they need. To prevent waste of the expensive supplement, the proper amount of supplemental mixture may be hand-fed, or the desired proportion of the supplemental mixture may be mixed with ground grain, and the mixture self-fed. (**1391**)

1. The trio mixture or modifications of it. See Articles **1418–1420** for discussions of the trio mixture and modifications which can be made in it. The original trio mixture contained 50 lbs. tankage, meat scrap, or fish meal; 25 lbs. good-quality alfalfa or other legume hay; and 25 lbs. linseed meal, soybean oil meal, cottonseed meal, or other high-protein supplement of plant origin. When tankage, meat scrap, and fish meal are high in price or limited in supply, the propor-

tion of animal-protein supplement may be reduced, as in the following mixtures. Also, if the pigs are well started on good pasture before being placed in dry lot, the proportion of legume hay may be reduced, as in supplemental mixture No. 4.

2. Tankage, meat scrap, or fish meal, 40 lbs.; legume hay, 25 lbs.; soybean oil meal, 20 lbs.; linseed meal, peanut oil meal, or cottonseed meal, 14 lbs.; salt, 1 lb.
3. Tankage, meat scrap, or fish meal, 20 lbs.; legume hay, 25 lbs.; soybean oil meal, 30 lbs.; linseed meal, cottonseed meal or peanut oil meal, 20 lbs.; ground limestone, 3 lbs.; salt, 2 lbs.
4. Tankage or meat scrap, 20 lbs.; fish meal, 20 lbs.; soybean oil meal, 40 lbs.; cottonseed meal, 10 lbs.; alfalfa leaf meal, 10 lbs.

B. Supplemental mixtures for self-feeding, free-choice, to pigs on good pasture, in addition to corn or grain sorghum, also self-fed, free-choice

1. One-half tankage, meat scrap, or fish meal, and one-half soybean oil meal, cottonseed meal, linseed meal, or other high-protein supplement of plant origin.
2. Tankage, meat scrap, or fish meal, 40 lbs.; soybean oil meal, 40 lbs.; linseed meal, cottonseed meal, or peanut oil meal, 19 lbs.; salt, 1 lb.
3. Tankage, meat scrap, or fish meal, 20 lbs.; soybean oil meal, 50 lbs.; linseed meal, cottonseed meal, or peanut oil meal, 24 lbs.; ground limestone, 4 lbs.; salt, 2 lbs.

C. Other rations for growing and fattening pigs not on pasture

1. Corn or grain sorghum, self-fed; skimmilk or buttermilk, 6 lbs. per head daily; choice alfalfa hay fed in rack.
2. Barley or wheat, self-fed; skimmilk or buttermilk, 4 to 5 lbs. per head daily; choice alfalfa hay fed in rack.
3. Corn or grain sorghum, self-fed; tankage, meat scrap, or fish meal, self-fed, free-choice; choice alfalfa hay fed in rack.

D. Other rations for growing and fattening pigs on good pasture

1. Corn or grain sorghum, self-fed; skimmilk or buttermilk, 3 to 4 lbs. per head daily.
2. Barley or wheat, self-fed; skimmilk or buttermilk, 2 to 3 lbs. per head daily.
3. Corn or grain sorghum, self-fed; tankage, meat scrap, or fish meal, self-fed, free-choice.

E. Mixtures for self-feeding or hand-feeding to growing and fattening pigs of various weights, which are in dry lot, without pasture

Any of the following mixtures are well suited for feeding to growing and fattening pigs which are in dry lot, without pasture. It will be noted that the proportion of protein supplements steadily decreases as the pigs become older.

Mixtures for growing and fattening pigs in dry lot

		Weaning to 50 lbs.	50 to 75 lbs.	75 to 125 lbs.	125 to 175 lbs.	Over 175 lbs.

POULTRY

Formula patterns for mashes for chickens

The following tables, based on present information concerning the nutrient requirements of chickens, show desirable formula patterns for mashes for various classes of chickens. (Hill, Norris, Scott, and Heuser, New York, Cornell Feed Service No. 48.)

Recommended formula patterns for all-mash poultry rations

Ingredients	Starter	Confinement grower	Layer	Breeder
	Lbs. per ton	Lbs. per ton	Lbs. per ton	Lbs. per ton
High-energy grain products (corn, wheat, wheat red dog, milo, oat meal)	800+	700+	900+	900+
Medium- and low-energy grain products (oats, barley, wheat flour middlings, wheat standard middlings, wheat bran)	0–400	0–600	0–500	0–500
Vegetable protein supplements (soybean oil meal, corn gluten meal, peanut oil meal)	400–600	350–450	250–350	200–300
Animal protein supplements, minimum levels (fish meal, fish solubles, meat scrap)	50–100	30– 80	—	50–100
Other B-vitamin carriers (dried milk products, dried yeast, distillers dried solubles, fermentation solubles)	50–100	30–100	—	50–100
Dehydrated alfalfa meal	50–100	50–100	50–100	50–100
Additional riboflavin, vitamin B_{12}, calcium pantothenate, niacin and vitamin A when needed *	+	+	+	+
Vitamin D_3 (feeding oils or D-activated animal sterols)	+	+	+	+
Calcium and phosphorus supplements (steamed bone meal, dicalcium phosphate, defluorinated phosphate, limestone)	30– 50	40– 60	100–120	100–120
Salt	5	5	10	10
Manganese sulfate (70% feeding grade)	0.4	0.4	0.4	0.4
Antibiotic feed supplement	+	?	—	—

* Refers to the use of supplements of riboflavin, calcium pantothenate, niacin, vitamin B_{12} and vitamin A sources of guaranteed vitamin content, or other vitamin-rich feedstuffs when the formula is otherwise deficient in any of these nutrients.

Recommended formula patterns for poultry mashes fed with grain

Ingredients	Growers: Confinement	Growers: Pasture	Layer	Breeder
	Lbs. per ton	Lbs. per ton	Lbs. per ton	Lbs. per ton
High-energy grain products (corn, wheat, wheat red dog, milo, oat meal)	600+	500+	600+	600+

Antibiotic feed supplement	+	?	–	–

* Refers to the use of supplements of riboflavin, calcium pantothenate, niacin, vitamin B_{12} and vitamin A sources of guaranteed vitamin content, or other vitamin-rich feedstuffs when the formula is otherwise deficient in any of these nutrients.

Laying hens and laying pullets

In addition to the mash and scratch grain in these rations, oyster shell or another source of calcium should be available at all times in hoppers. Plenty of fresh water should also be furnished.

Where alfalfa meal is used as a source of vitamin A (carotene), the recommendations are based on alfalfa meal containing 100,000 International Units of vitamin A potency per pound. If alfalfa meal of unknown or low content of vitamin A value is used, additional vitamin A supplementation will be necessary.

A. Laying mashes with which an equal weight of grain is fed

1. Ground yellow corn, 795 lbs.; ground wheat, 300 lbs.; soybean oil meal, 540 lbs.; fish meal, 50 lbs.; meat and bone scrap, 50 lbs.; distillers dried corn solubles, 50 lbs.; alfalfa meal (high-quality), 100 lbs.; dicalcium phosphate, 60 lbs.; ground limestone, 40 lbs.; iodized salt, 15 lbs.; manganese sulfate (70%), 0.5 lb.; riboflavin, 1,500 milligrams; vitamin A, 2,000,000 I.U. (in addition to the high-quality alfalfa meal); vitamin D, 1,360,000 I.C.U.; total, 2,000.5 lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.)
2. Ground barley, 200 lbs.; ground yellow corn, 400 lbs.; ground milo, 200 lbs.; ground wheat, 200 lbs.; wheat bran, 300 lbs.; fish meal, 158 lbs.; meat and bone scrap, 50 lbs.; soybean oil meal, 250 lbs.; dried whey, 50 lbs.; dehydrated alfalfa meal, 150 lbs.; ground limestone, 40 lbs.; salt, 10 lbs.; manganese sulfate, 0.25 lb.; riboflavin, 1 gram; vitamin D supplement, 2 lbs.; total, 2,010 lbs. (California Egg Laying Test, 1954.)
3. Ground wheat, 600 lbs.; ground yellow corn, 300 lbs.; ground barley, 180 lbs.;

pulverized oats, 200 lbs.; meat scrap, 50 lbs.; fish meal, 50 lbs.; dried buttermilk or skimmilk, 50 lbs.; soybean oil meal, 374.5 lbs.; dehydrated alfalfa meal, 80 lbs.; ground limestone, 40 lbs.; steamed bone meal or equivalent, 55 lbs.; iodized salt, 15 lbs.; manganese sulfate, 0.5 lb.; vitamin A oil (10,000 I.U. per gram) 2 lbs.; dry vitamin D supplement (1,650 I.C.U. per gram), 2 lbs.; plus riboflavin, vitamin B_{12}, and antibiotic supplements. (Ontario Agricultural College, Circular 142A.)

B. All-mash rations for laying hens

1. High-energy mash. Ground yellow corn, 1,150 lbs.; ground wheat, 300 lbs.; soybean oil meal, 280 lbs.; fish meal, 20 lbs.; meat and bone scrap, 50 lbs.; distillers dried corn solubles, 30 lbs.; alfalfa meal (high-quality), 50 lbs.; dicalcium phosphate, 30 lbs.; ground limestone, 80 lbs.; iodized salt, 10 lbs.; manganese sulfate, 0.4 lb.; riboflavin, 600 milligrams; vitamin D, 680,000 I.C.U.; total, 2,000+ lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.)
2. High-energy mash. Ground yellow corn, 1,223 lbs.; wheat standard middlings, 250 lbs.; soybean oil meal, 200 lbs.; meat and bone scrap, 100 lbs.; fish meal, 40 lbs.; dehydrated alfalfa meal (100,000 I.U. per lb.), 50 lbs.; butyl fermentation product (250 milligrams riboflavin per pound), 20 lbs.; steamed bone meal, 40 lbs.; ground limestone, 60 lbs.; salt, 10 lbs.; manganese sulfate, 0.25 lb.; vitamin A and D feeding oil (2,000 I.U. A and 400 I.C.U. D_3 per gram), 5 lbs.; vitamin B_{12} supplement (3 milligrams B_{12} per pound), 2 lbs.; niacin, 20 grams; total, 2,000.25 lbs. (Singsen, Matterson, and Kozeff, Conn. (Storrs) Bul. 286.)
3. Ground yellow corn, 1,125 lbs.; ground barley or pulverized oats, 100 lbs.; wheat standard middlings, 200 lbs.; soybean oil meal, 250 lbs.; fish meal, 25 lbs.; meat and bone scrap, 50 lbs.; dehydrated alfalfa meal (17% protein, 100,000 I.U. per lb.), 75 lbs.; distillers dried solubles, 50 lbs.; dicalcium phosphate or equivalent, 32 lbs.; ground limestone, 75 lbs.; iodized salt, 10 lbs.; dry vitamin D supplement (1,500 I.C.U. per lb.), 1 lb.; manganese sulfate, 0.25 lb.; niacin, 18 grams; vitamin B_{12} supplement contributing not less than 6 milligrams of vitamin B_{12} per ton of mash; approved antioxidant; total, 1,993.25 lbs. (New England Conference, 1954.)
4. Ground wheat, 1,100 lbs.; ground yellow corn, 455 lbs.; meat and bone scrap, 50 lbs.; fish meal, 30 lbs.; dried buttermilk or skimmilk, 30 lbs.; soybean oil meal, 200 lbs.; dehydrated alfalfa, 50 lbs.; steamed bone meal or equivalent, 35 lbs.; ground limestone, 40 lbs.; iodized salt, 10 lbs.; manganese sulfate, 0.25 lb.; vitamin A oil (10,000 I.U. per gram), 1 lb.; dry vitamin D (1,650 I.C.U. per gram), 1 lb.; plus riboflavin, vitamin B_{12}, and antibiotic supplements. (Ontario Agricultural College Circular 142A.)

C. Mashes for breeders producing hatching eggs

1. Mash to be fed with grain. Ground yellow corn, 735 lbs.; ground wheat, 300 lbs.; soybean oil meal, 430 lbs.; fish meal, 80 lbs.; meat and bone scrap, 100 lbs.; dried whey, 100 lbs.; alfalfa meal (high-quality), 100 lbs.; distillers dried corn solubles, 50 lbs.; dicalcium phosphate, 50 lbs.; ground limestone, 40 lbs.; iodized salt, 15 lbs.; manganese sulfate, 0.5 lb.; riboflavin, 3,200 milligrams; vitamin B_{12}, 3 milligrams; vitamin A, 2,000,000 I.U. (in addition to the high-quality alfalfa meal); vitamin D, 1,360,000 I.C.U.; calcium pantothenate, 4,000 milligrams; total, 2000+ lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.
2. All-mash ration. Ground yellow corn, 1,120 lbs.; ground wheat, 300 lbs.; soybean oil meal, 220 lbs.; fish meal, 50 lbs.; meat and bone scrap, 50 lbs.; dried whey, 50 lbs.; alfalfa meal (high-quality), 50 lbs.; distillers dried corn solubles, 50 lbs.; dicalcium phosphate, 20 lbs.; ground limestone, 80 lbs.; iodized salt, 10 lbs.; manganese sulfate, 0.4 lb.; riboflavin, 1,500 milligrams; vitamin B_{12}, 2 milligrams; vitamin D, 680,000 I.C.U.; calcium pantothenate, 2,000 milligrams; total, 2,000+ lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.)

D. Starter mashes for chicks

1. Ground yellow corn, 925 lbs.; ground wheat, 300 lbs.; soybean oil meal, 475 lbs.; fish meal, 50 lbs.; meat and bone scrap, 50 lbs.; dried whey, 50 lbs.; alfalfa meal (high-quality), 50 lbs.; distillers dried corn solubles, 50 lbs.; dicalcium phosphate, 10 lbs.; ground limestone, 35 lbs.; iodized salt, 5 lbs.; manganese sulfate, 0.4 lb.; riboflavin, 400 milligrams; vitamin B_{12}, 5 milligrams; vitamin D, 540,000 I.C.U.; calcium pantothenate, 800 milligrams; plus antibiotic feed supplement; total, 2,000+ lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.)
2. Ground yellow corn, 1,100 lbs.; wheat standard middlings, 100 lbs.; soybean oil meal, 500 lbs.; fish meal, 100 lbs.; alfalfa meal, 60 lbs.; distillers dried solubles, 50 lbs.; butyl fermentation product, 20 lbs.; dicalcium phosphate or equivalent, 24 lbs.; ground limestone, 30 lbs.; iodized salt, 10 lbs.; manganese sulfate, 0.5 lb.; dry vitamin D supplement (1,500 I.C.U. per gram), 0.5 lb.; niacin, 18 grams; choline chloride, 2.5 lbs.; plus antibiotic-vitamin B_{12} feed supplement and approved antioxidant. (New England College Conference, 1954.)

E. Grower mashes

1. Without pasture, all-mash ration. Ground yellow corn, 1,095 lbs.; ground wheat, 300 lbs.; soybean oil meal, 370 lbs.; fish meal, 30 lbs.; meat and bone scrap, 50 lbs.; dried whey, 25 lbs.; alfalfa meal (high-quality), 50 lbs.; distillers dried corn solubles, 25 lbs.; dicalcium phosphate, 20 lbs.; ground limestone, 30 lbs.; iodized salt, 5 lbs.; manganese sulfate, 0.4 lb.; vitamin B_{12}, 2 milligrams; vitamin D, 270,000 I.C.U.; calcium pantothenate, 2,000 milligrams; plus antibiotic feed supplement, if desired; total, 2,000+ lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.)
2. Mash to be fed with grain, without pasture. Ground yellow corn, 840 lbs.; ground wheat, 300 lbs.; soybean oil meal, 470 lbs.; fish meal, 50 lbs.; meat and bone scrap, 50 lbs.; dried whey, 50 lbs.; alfalfa meal, 100 lbs.; distillers dried corn solubles, 50 lbs.; dicalcium phosphate, 40 lbs.; ground limestone, 40 lbs.; iodized salt, 10 lbs.; manganese sulfate, 0.5 lb.; vitamin B_{12}, 5 milligrams; vitamin D, 540,000 I.C.U.; calcium pantothenate, 3,000 milligrams, plus antibiotic feed supplement, if desired; total, 2,000+ lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.)
3. Mash to be fed with grain on good pasture. Ground corn, 665 lbs.; ground wheat, 600 lbs.; soybean oil meal, 600 lbs.; dicalcium phosphate, 55 lbs.; ground limestone, 60 lbs.; iodized salt, 20 lbs.; manganese sulfate, 0.5 lb.; plus antibiotic feed supplement, if desired; total, 2,000+ lbs. (Hill, Norris, Scott, and Heuser, N.Y., Cornell Feed Service No. 48.)

TABLE VIII. GRAIN FEEDING TABLES FOR DAIRY COWS

It has been emphasized previously that the amount of concentrates, or "grain mixture," to be fed each cow in a herd should be adjusted to her actual production of milk and fat. Otherwise, some cows may be wastefully overfed and others seriously underfed. (**1001**) The common "thumb rules" often used for estimating the amount of grain mixture that should be fed to the various cows are not accurate guides to their real requirements. (**1011**) The amount of grain required by any cow can be determined by computing a balanced ration according to the feeding standards, but to do this for the individual cows in a herd takes considerable time.

The following tables have therefore been prepared to indicate how many pounds of a good concentrate mixture, or so-called "grain mixture," are required by cows producing various amounts of milk of different fat percentages. The first of these tables, Table VIIIa, is for cows not on pasture, and the second one, Table VIIIb, is for cows which are on pasture. Sufficient amounts of grain mixture are advised to meet the higher set of recommendations in the Morrison feeding standards. (Appendix Table III.) When grain and other concentrates are very high in price in comparison with roughages, then it may be advisable to feed smaller amounts of grain mixture than shown in these tables. (**1025–1027**)

The amounts of grain mixture advised are for mature cows during the chief part of the lactation period. As has been emphasized previously, the amount of grain mixture should be increased very gradually after a cow freshens. (**1031**) Three weeks or more should be taken to get high producers on full feed. Even at that time and for a few weeks thereafter, high producers are often unable to consume safely as much grain as would be required to produce the amount of milk they are yielding. They therefore draw temporarily on the store of nutrients in their bodies.

During the last 2 to 3 months of pregnancy, good cows should be fed somewhat more grain mixture than shown in the tables. This is to provide the additional nutrients needed for the development of the unborn calf and to get the cow into proper condition for the next lactation. (**1082**) Since heifers need additional feed for the growth of their own bodies, it is wise to feed them a little more liberally than the amounts shown in the tables. (See Appendix Table III.)

Table VIIIa. Grain feeding table for cows not on pasture.—The amount of the grain mixture that it is necessary to feed daily to any particular cow will depend not only on the amount of milk she gives and on its richness in fat, but also on the amount and quality of the roughage she consumes. Also, it will depend to some extent on her live weight.

This table therefore gives recommendations for three different rates of roughage feeding, as shown by the first three columns. The second column, in bold-faced type, gives the figures for the most common rate of feeding roughage to dairy cows. This rate is to feed approximately 2 lbs. of good hay daily per 100 lbs. live weight, or the equivalent in other good roughage (for example, 1 lb. of good hay and 3 lbs. of silage).

When cows are fed *very liberally* on roughage of *excellent quality* and the allowance of grain is restricted to their needs, they will consume per 100 lbs. live weight about 2.5 lbs. of hay equivalent. The first column of figures is designed to fit these conditions.

The third column of figures is for use when cows are fed a scanty allowance of good roughage, or when they are fed as much poor roughage as they will consume without undue waste. This column is designed for use when cows consume only about the equivalent of 1.5 lbs. of good hay daily per 100 lbs. live weight.

In using the table, first estimate approximately the number of pounds of hay equivalent the cows are actually consuming daily per 100 lbs. live weight, after deducting the wastage. In making this estimate, use the following conversion factors for converting the amounts of other roughages actually consumed

into the equivalent amounts of good hay. (Good-quality legume hay or well-cured, early-cut grass hay is taken as the standard.)

Fair-quality hay	80 per cent
Poor-quality hay; cut or shredded corn or sorghum stover	60 per cent
Good silage; potatoes.......	33 per cent
Mangels; rutabagas; cabbage	20 per cent
Oat straw; barley straw	50 per cent

After estimating the pounds of good hay equivalent consumed per 100 lbs. live weight, then use the particular one of the first three columns that most nearly fits the rate of roughage feeding. Go down this column to the amount of milk given by the particular cow, and then follow the horizontal row of figures across the table to the right until the column is reached for milk having the percentage of fat nearest to that of the milk produced by the cow. The figure in this column shows the pounds of grain mixture to be fed daily to the cow.

To illustrate the use of the table, let us assume that a cow yielding 36 lbs. of milk containing 3.5 per cent fat is being fed approximately 2.0 lbs. of good hay equivalent per 100 lbs. live weight. We go down the second column, which is for this rate of roughage feeding, until we come to the figure 36. We then go horizontally to the right across the table until we reach the column for 3.5 per cent fat, where we find the figure 10.8. Therefore this cow should be fed 10.8 lbs. of a good grain mixture daily to meet her requirements.

Adjustment for difference in live weights.—The amounts of grain mixture required by different cows producing the same amount and richness of milk depend somewhat on their respective live weights. When fed roughage at the usual rate, for each additional 100 lbs. a cow weighs in comparison with a smaller cow, she will consume approximately 2 lbs. more hay equivalent. This furnishes about 1.0 lb. total digestible nutrients. However, for each 100 lbs. increase in body weight, she requires for maintenance only about 0.65 to 0.70 lb. more total digestible nutrients. Therefore, for each 100 lbs. of additional body weight, she will have available for milk production approximately 0.35 to 0.30 lb. of total digestible nutrients. This will save about 0.4 lb. of grain mixture.

This table and Table VIIIb have been computed for cows of the following average weights:

For 3.0, 3.5 and 4.0% milk	1,200 lbs. weight
For 4.5 and 5.0% milk	1,000 lbs. weight
For 5.5 and 6.0% milk	850 lbs. weight

There will be no important error in using the tables for cows of other weights, unless the difference in weight is too great. If greater accuracy is desired, 0.4 lbs. should be deducted from the amount of grain mixture recommended in the table, for each 100 lbs. the weight of a given cow exceeds the standard weights shown above. If the weight of a cow is considerably less than these standard weights, 0.4 lb. should be added to the recommended amount of grain mixture for each 100 lbs. she weighs less than the standard used in the table for cows producing milk containing the given percentage of fat.

Table VIIIb. Grain feeding table for cows on pasture.—This table shows the approximate amounts of a good concentrate mixture, or "grain mixture," required per head daily by cows on excellent, good, and fair pasture. The method of using this table is similar to that for Table VIIIa.

The column of figures for excellent pasture is to be used for cows which are on pasture that provides an abundance of very palatable, nutritious forage. Such forage is furnished by usual grass pasture only during the flush of growth in late spring and early summer. Only pasture that is liberally fertilized and also well managed will generally furnish such pasturage later in the season.

The second column of figures, which is for good pasture, is for use when the cows have a plentiful supply of good pasturage, but when the pasture can hardly be called excellent. On such pasture the

cows must be able to secure somewhat more feed from the pasture than they do from a full feed of good hay and average silage in winter.

The third column of figures is for use when the cows are on fair pasture, but not on pasture that is distinctly poor. On poor pasture cows will need fully as large an allowance of grain mixture as when fed roughage at the rate shown in the third column of Table VIIIa.

If a cow differs considerably in live weight from the weight used in computing this table, adjustments in the amount of grain mixture should be made, as previously stated in this explanation.

These tables have been adapted from tables prepared by Mr. J. W. Avery, formerly in charge of the Central Dairy Record Club Laboratory of the New York State College of Agriculture, and by Professor W. T. Crandall of the Department of Animal Husbandry of the New York State College of Agriculture, Cornell University.

TABLE VIIIa. Grain feeding table for cows not on pasture

Hay equivalent consumed per 100 lbs. of live weight daily			Total pounds of grain mixture or concentrates to feed						
2½ lbs. Very liberal feeding of good roughage	2 lbs. Usual rate of feeding good hay or good hay and silage	1½ lbs. Feeding scanty amount of good roughage or feeding poor roughage	Percentage of fat in milk						
Milk produced daily, pounds			3.0%	3.5%	4.0%	4.5%	5.0%	5.5%	6.0%

Table IX. Estimating Weights of Dairy Cattle from Heart Girths

In computing balanced rations for dairy cows and other dairy cattle, it is necessary to know their approximate live weights. If one does not have suitable scales available for weighing the cattle, their weights can be estimated approximately by measuring the heart girth, or chest girth. In finding the heart girth, an accurate tape measure should be placed around the animal directly back of the front legs. The animal should stand squarely on all four legs.

A mature cow is heavier than an immature cow having the same heart girth. Investigations by the Illinois and Nebraska Stations show that the most accurate estimate of the live weights of cows during the first month of lactation can be made if the number of inches shown in the first table is added to the actual heart girth. (Gaines, Davis, and Morgan, Journal Dairy Science, 24, 1941, pp. 983–992.) This gives the modified heart girth.

Add the following number of inches to the actual heart girth

	Jerseys Inches	Guernseys Inches	Ayrshires Inches	Holsteins Inches
Less than 3 years old	0	2	2	6
3 to 4 years old	2	4	4	8
5 years old or more	2	5	5	9

After the actual heart girth has been modified by using the preceding table, the estimated heart girth is found in the table below:

Estimated live weights of dairy cows from modified heart girths

Mod. heart girth	Weight	Mod. heart girth	Weight	Mod. heart girth	Weight	Mod. heart girth	Weight	Mod. heart girth	Weight
Inches	Lbs.	Inches	Lbs.	Inches	Lbs.	Inches	Lbs.	Inches	Lbs.
50	475	60	666	70	886	80	1134	90	1411

58	626	68	840	78	1082	88	1353	98	1651
59	646	69	863	79	1108	89	1382	99	1683

The approximate live weights of dairy heifers may be estimated from the actual heart girths by the use of the following table, based on studies by the Nebraska and Missouri Stations. (Davis, Morgan, Brody, and Ragsdale, Nebraska Research Bulletin 91.)

Estimated weights of dairy heifers having various heart girths

Heart girth	Weight	Heart girth	Weight	Heart girth	Weight	Heart girth	Weight	Heart girth	Weight
Inches	Lbs.	Inches	Lbs.	Inches	Lbs.	Inches	Lbs.	Inches	Lbs.

Tables X. Amino Acid Content of Certain Feeds

Amino acids in feeds.—The information concerning the amounts of the essential amino acids in feeds is still very limited, because of the expense and difficulty in making such determinations. The following tables show the approximate content of these amino acids in important feeds, so far as data are available. Very little information has been secured concerning the amounts of the essential amino acids in roughages, except alfalfa meal and alfalfa hay.

It must be borne in mind that for most feeds amino acid determinations have been made on only a few lots of the feed, and the results have often differed appreciably. However, the tables indicate which feeds are low and which are higher in the amino acids that are most apt to be deficient in rations for non-ruminants, especially pigs and poultry. These amino acids are lysine, tryptophan, and methionine.

As cystine can partially replace methionine in a ration, the tables also state the approximate content of cystine, where cystine determinations have been reported. Cystine itself is not an essential amino acid.

The first table, Table Xa, states the percentages of the several amino acids in the entire feed, as fed. The second table, Table Xb, gives the percentages of the amino acids in the **protein** of each feed.

Because feeds differ so widely in percentage of total protein they contain, Table Xb indicates better than Table Xa whether the protein in a particular feed is a good or a poor source of the important essential amino acids.

Sources of data.—The data presented in these tables are based on a compilation of available data, made by the author. Much data has been provided by the recent compilation of analyses of by-product concentrates made by Donald E. Miller, technical secretary of the Committee on Feed Composition of the National Research Council. The author is a member of this committee and cooperated in the compilation by supplying data he had compiled. This compilation has just been published in preliminary form by the National Research Council.

Analyses have been included from the following sources: Williams, Essential Amino Acid Content of Animal Feeds, New York (Cornell) Memoir 337, 1955; Almquist, Proteins and Amino Acids in Nutrition, edited by Sahyun, 1948, p. 231; Schweigert, Texas, Poultry Science, 27, 1948, pp. 223–227; Block and Bolling, The Amino Acid Composition of Proteins and Foods, 1945.

The author has also compiled amino acid analyses published in the bulletins and reports of the agricultural experiment stations and in other scientific publications.

Table Xa. Percentages of amino acids in certain feeds

Table XI. Productive and Metabolizable Energy of Feeds for Poultry

In formulating rations for poultry, productive-energy values, or net-energy values, of feeds are often used. (1530) The first column of figures in the following table gives the productive-energy values of the more important poultry feeds, as estimated by Fraps from his experiments. (Fraps, Texas Bul. 678.) The values are stated in terms of Calories of productive energy per pound of feed.

The second column of figures gives the productive-energy values of these feeds, as recently computed by Titus from the data of Fraps and others and from the digestible nutrients for poultry in these feeds. (Titus, Scientific Feeding of Chickens, 2nd Edition, 1955.)

The last column of figures gives the metabolizable-energy values of these feeds. As stated in Chapter XXXVII, recent studies indicate that metabolizable-energy values are more reliable than productive-energy values for poultry. (1532)

The metabolizable-energy values marked with an asterisk are values actually determined in recent New York experiments. (Hill, N.Y. mimeo. rpt., 1956; Anderson, Proceedings 1956 Cornell Nutrition Conference for Feed Manufacturers.) The values marked with a dagger are values computed by Titus from the digestible nutrients for poultry in these feeds, and from other data. (Titus, Scientific Feeding of Chickens, 2nd Edition, 1955.)

Hominy feed	831	...	...
Kafir	1,059	1,082	1,502 †
Linseed meal, exp.	571	507	692 †
Liver meal	1,092	1,031	1,373 †
Meat scrap, 55% protein	724	949	1,249 †
Meat and bone scrap, 50% protein	724	874	800 *
Milk, cow's	...	203	284 †
Millet, proso	985	975	1,362 †

TABLE XI. Productive and metabolizable energy of feeds for poultry—*continued.*

Feeding stuff	Productive energy, Fraps' values	Productive energy, Titus' values	Metabolizable energy
	Cal. per lb.	Cal. per lb.	Cal. per lb.
Milo	1,119	1,099	1,470 *
Molasses, cane	714	. . .	. . .
Oats	760	810	1,220 *
Oat meal or groats	1,151	1,162	1,630 *
Peanut meal	861	856	1,134 †
Potatoes	. . .	215	321 †
Rice, rough	777	786	1,216 †
Rice bran	717	698	1,072 †
Rice polishings	984	1,044	1,555 †
Rye	814	886	1,319 †
Skimmilk, dried, not over 5% of mash	525	765	1,232 †
Skimmilk, liquid	. . .	107	145 †
Soybeans, cooked	. . .	1,023	. . .
Soybean oil meal, solvent, 50% protein	. . .	790	1,142 †
Soybean oil meal, solvent, 44% protein	565	761	1,000 *
Sunflower-seed oil meal, unhulled	. . .	580	772 †
Sweet potatoes	. . .	269	425 †
Tankage, 60% protein	676	814	1,198 †
Wheat	1,024	897	1,490 *
Wheat bran	478	494	510 *
Wheat gray shorts, or flour middlings	720	756	1,190 *
Wheat red dog	983	. . .	1,380 *
Wheat standard middlings, or brown shorts	581	694	810 *
Whey, dried, not over 5% of mash	490	786	1,242 †
Yeast, brewers', dried	476	572	1,123 †
